Printed and published by the British Medical Association, at their Office, Tavistock Square, in the Parish of St. Pancras, in the County of London.

of the stomach on clinical grounds is not supported by any definitely positive findings on physical examination (especially with *x* rays), before resorting to exploratory laparotomy the effect of careful diet and medical treatment may be first tried. Sir Thomas Horder advises laparotomy in any gastric case where there is a failure to gain weight or at any rate to maintain weight after the end of the third week of efficient medical treatment. It must not, however, conversely, be too readily assumed that a definite gain of weight under such conditions excludes the presence of a carcinoma, and Dr. Hurst believes that the majority of patients with carcinoma of the stomach gain weight after a fortnight in bed with careful dieting.

Operation for Diagnosis.

Exploratory laparotomy must be more generally adopted than is at present the case if carcinoma of the stomach is to be discovered at a stage sufficiently early to offer a hope of radical rure. Whilst I do not wish to be understood as advocating a wholesale resort to this method of ensuring the diagnosis of all indefinite gastric complaints, yet I would certainly recommend that exploratory laparotomy should be performed where the suspicion of carcinoma on clinical grounds is strong, even if unsupported by any definitely positive finding on physical examination, and where careful medical treatment fails either to increase the weight or to maintain any initial increase. In such cases, even if the operation should, fortunately for the patient, fail to disclose a carcinoma, yet it will generally happen that some other cause for the symptoms will be discovered and surgically remedied.

Operative Treatment.

In the operative treatment of gastric carcinoma one should always aim at a radical operation, and the first question to decide in any given case is whether any condition be present which puts out of court any hope of a radical removal. Such contraindication may be capable of discovery (*a*) before laparotomy, or (*b*) only after the abdomen has been opened. Apart from conditions of a general and constitutional nature such as would preclude any severe operation, certain local conditions are definite contraindications: (1) enlargement of the liver, especially if associated with "umbilicated" nodules; (2) ascites of a degree sufficient to be detected clinically; (3) enlarged glands in the supraclavicular region, particularly on the left side; (4) secondary peritoneal deposits engrafted, by gravity, upon the pelvic peritoneum and detectable clinially on rectal examination as an induration of the recto-vesical pouch (a rectal examination should never be omitted when considering the feasibility of radical operation in any abdominal malignant condition, and the detection of induration in the recto-vesical pouch not infrequently prevents a useless operation); and (5) a mass palpable through the abdominal wall is frequently held to contraindicate radical measures, but does not necessarily do so. It depends more upon the question of fixity than of palpability. A palpable mass, if fixed, would certainly prevent a radical operation, but not so if mobile.

Contraindicatiofis to radical operation discoverable only after a laparotomy are: (1) small secondary deposits in the liver—these are detectable only when near the surface; (2) peritoneal deposits on the peritoneum of the recto-vesical (or recto-vaginal) pouch too small to be felt per rectum: (3) secondary glandular deposits beyond reach of the operative field, at the hilum of the liver, superior mesenteric, meso-colic, or lumbar glands: and (4) fixity of the stomach to other parts, especially liver and pancreas—such adhesion may be inflammatory only, and superficial slices may be removed from the liver and pancreas with the growth.

If, owing to the presence of any of these contraindications radical extirpation is considered impossible, the next question to decide is whether a palliative operation is advisable. Gastro-enterostomy, except where the growth is near the pylorus, and where obstruction is actually in existence or threatens to be so shortly, gives such a small measure of relief as to be scarcely worth performing. Any palliative operation for carcinoma other than of the pyloric portion should take the form of a partial gastrectomy, and, provided that the whole of the disease in the stomach can be removed, is well worth while undertaking even though disease be left in the glands, peritoneum, or liver. The immediate results are often remarkably good, and there is always the off-chance that an error in the original diagnosis, or in one's estimate of the extent of the disease, may lead to a pleasant surprise in the form of a permanent cure.

If no contraindications exist radical extirpation should be attempted. A consideration of the lymphatic arrangements shows that the minimum amount of the stomach to be removed lies between a line prolonging downwards the right edge of the oesophagus to the greater curvature and a line one inch beyond the pylorus—that is, the whole of the lesser and about one-half of the greater curvatures are removed. All operations of the type of Billroth No. 1 are, therefore, excluded; Schoemaker's operation is also unsuitable since it leaves too much of the greater curvature. Only operations of the type of Billroth No. 2 or the Polya modification of it—in which the divided stomach is anastomosed laterally to the commencement of the jejunum ("end-to-side" anastomosis), the duodenal stump being completely closed—are worthy of consideration, but time will not permit me to refer further to the technical details of these radical procedures.

CANCER OF THE COLON.

The early diagnosis of cancer of the colon is particularly important since it is one of the less virulent types of carcinoma; it usually runs a slow course, the invasion of the lymphatic vessels and glands is delayed, metastasis is comparatively rarely found and then chiefly in advanced cases. Too much reliance cannot, however, be placed on these features, since occasionally secondary deposits in the liver have been met with even at a very early period. There are two main types of carcinoma seen in the colon: (1) a "cauliflower" or fungating type, which rarely causes any marked degree of obstruction of the bowel, but tends rather to be associated with ulceration, and which is situated mostly in the right half of the colon; and (2) the "ring-structure" type, most frequent in the left half, associated with marked obstruction, and rarely involving any large vertical extent of the bowel.

In the decade 1913-22 inclusive there were 485 cases of malignant growths of the colon admitted to the Manchester Royal Infirmary, located as follows:

Malignant Growths of the Colon (Manchester Royal Infirmary).

Segment of Colon.	No. of Malignant Growths.	Percentage Frequency.
Caecum	25	5.1
Ascending colon ...	11	2.2
Hepatic flexure ...	7	1.4
Transverse colon ...	22	4.5
Splenic flexure ...	39	8.0
Descending colon ...	12	2.4
Sigmoid colon ...	143	29.4
Rectum	226	46.5
Total ...	485	

Of these 485 cases 173 were associated with acute obstruction (35.6 per cent.). Of the growths causing obstruction, 13.2 per cent. were located in the right half of the colon and 86.7 per cent. in the left half—that is, there is a 6.5 to 1 chance of a malignant growth that has caused obstruction being on the left side. Of all causes of acute colonic obstruction carcinoma constitutes 87.9 per cent.

If in any given case of acute intestinal obstruction the site of such obstruction can be located to the colon, and if, further, we can exclude strangulated hernia and acute intussusception as the cause (the former presenting a definite external swelling at one of the hernial orifices, the latter occurring at a very early period of life and having characteristic symptoms), then there remains a 91 per cent. likelihood of the cause being a malignant growth—that is, a 9 to 1 chance.

Symptoms.

The earliest symptoms of carcinoma of the colon are those indicative of some defective action of the bowels, and are of especial importance in those whose bowels have always previously "acted like clockwork." The first change noted is usually a steadily increasing difficulty in

obtaining a satisfactory action of the bowels, necessitating the use of purgatives in gradually increasing doses. Periods of increasing constipation frequently alternate with short periods of diarrhoea, the gradual accumulation of faeces above the malignant stricture acting as an irritant and setting up a local intestinal catarrh with increased secretion of mucus; this causes a softening of the faecal mass, and leads to its expulsion in several frequently repeated small evacuations mixed with much mucus and occasionally with a little blood even in an early stage. Later the more powerful peristalsis of the hypertrophied bowel proximal to the stricture causes colicky pains, at first very slight, but gradually developing into definite "cramps." Such are often induced by the taking of food, since the entrance of food into the stomach starts peristalsis in the intestines; on this account these pains are often ascribed to "indigestion," and the stomach instead of the bowel is considered to be at fault. This increased peristalsis sometimes causes a desire to go to stool after each meal—a very suspicious sequence—when mucus only, or possibly a slight amount of blood in addition, is passed. Sooner or later these colicky pains are associated with rumblings of flatus, and these may become so loud as to be audible to other persons in the room. In many cases the patient volunteers the information that he feels the griping pains to cease always at the same site—where also the "rumbling" starts—and he can thus, with remarkable accuracy, indicate the location of the obstructing growth. Needless to say, these colicky pains are all made much worse by the taking of a purgative. After a time abdominal distension follows from the accumulation of flatus and faeces proximal to the stricture and is at first localized to the bowel just above it, so that, if seen at this stage, a further clue may be obtained to the site of the growth. The "cauliflower" type of neoplasm, such as is met with chiefly in the caecum or the right half of the colon, is not usually associated with these evidences of obstruction, but tends to ulcerate early and to lead to diarrhoea and the passage of mucus and blood per anum, thus simulating mucous colitis; it is in this type that blood may be lost in small amounts over a long period of time and produce so high a degree of anaemia as to lead to an erroneous diagnosis of pernicious anaemia.

The early physical signs are those of gradually increasing distension and hypertrophy of the bowel proximal to the site of the growth, the outlines of individual dilated coils being visible under the abdominal wall together with a visible peristaltic wave passing at intervals along them. Even when not actually visible the passage of the peristaltic wave can often be appreciated by palpation over the distended bowel as a very definite temporary hardening of its wall, followed by relaxation and softening—the so-called "palpable peristalsis." This is best elicited over the caecum, this portion of the colon, particularly if the ileo-caecal valve be competent, being that which is most distended and which is, in consequence, the first to rupture in advanced degrees of obstruction. Too much stress cannot be laid upon the diagnostic importance of this combination of dilated intestinal coils with visible (or palpable) peristalsis—it invariably denotes the existence of intestinal obstruction. In the normal state neither peristaltic waves nor the outlines of individual coils of bowel are ever visible through the abdominal walls, though rarely these phenomena may be seen beneath the thinned-out covering of large ventral herniae, in cases of wide divarication of the recti muscles, and also in extreme degrees of emaciation. Even in these instances, however, the coils observed are of normal size and not distended, and are not really exceptions to the rule that whenever we can see clearly the outlines of coils of *distended* intestine, together with a peristaltic wave passing along them, we can diagnose intestinal obstruction of a subacute or chronic character with absolute confidence. At first the abdominal distension is confined to the course of the colon and is noted chiefly in the flanks; later on (and almost from the first in those cases where the ileo-caecal valve is incompetent) the distension affects the lower coils of the ileum, which become folded in a more or less transverse direction, constituting the well known "ladder pattern" of the abdomen.

Auscultation—a much neglected method of physical examination of the abdomen—is often extremely useful if one is conversant with the character and site of the normal intestinal sounds and of the alterations in tone, intensity, and distribution met with in obstructive conditions.

In many cases a tumour may be felt somewhere along the course of the colon, and this is more frequently possible in the right half of the colon and with the "cauliflower" type of growth. A palpable swelling must not, however, always be assumed to be the growth itself, and this specially applies to the annular type usually met with in the left half of the colon, which is of insignificant vertical extent and too small to be palpable from without; the swelling actually felt in such circumstances is more likely to prove a mass of hardened faeces collected just above the malignant stricture, and may completely disappear with purgatives or after an enema; such disappearance must not, therefore, be considered, as it unfortunately is so frequently allowed to do, as excluding the presence of growth, rather should it induce a more careful search for any possible organic cause of such holding up of faeces. A secondary malignant deposit in the liver, and even the hypertrophied and distended caecum (particularly if felt when stiffened by the passage of the peristaltic wave), have been mistaken for a growth in the colon. A careful rectal examination should always be carried out, even though, except in rectal growths which we shall separately consider, one cannot expect to feel the actual growth itself. In the case of growths situated low down in the sigmoid colon, however, it is sometimes possible to detect the mass by palpation through the anterior rectal wall; in other cases the indurated and infiltrated peritoneum of the pouch of Douglas, often present in advanced abdominal malignancy, irrespective of its primary site, may be recognized; and in others, again, the characteristic "ballooning" of the rectum so often associated with growths in the sigmoid or descending colon can be detected.

The sigmoidoscope is a very valuable aid in the diagnosis of growths in the lower sigmoid, but requires care and experience in its use and in the interpretation of what is seen; through it small portions of a doubtful growth may be snipped off for microscopical examination. Multiple papillomata may be seen, and are so frequently associated with malignant growths higher up the colon that their presence, if associated with any other symptom or sign of cancer of the colon, is sufficient to justify an exploratory laparotomy.

Of all the methods of physical examination of the colon the most important is that of radiography after a barium meal, and particularly after a barium enema. The barium meal is useful in ascertaining the general function of the colon, but the barium enema is of greater service for the localization of an obstruction in the colon. The enema is administered with the patient lying flat, and, if no obstruction be present in the colon, it should travel round to the caecum within a few minutes. It must, however, be borne in mind that a growth producing partial obstruction only does not necessarily interfere with the passage of the barium enema, and may therefore be easily overlooked. Moreover, a malignant stricture in the sigmoid may be obscured by an overlying barium-filled coil, especially when a barium meal has been given; or, as Pannett has pointed out,[3] if the affected bowel lies with its axis in the direction of the x rays the defect in the barium shadow will not be seen. The findings of barium meals and enemata should be verified by a second examination to minimize the possibility of error.

Treatment of Cancer of the Colon.

In the treatment of carcinoma of the colon the ideal at which we should aim is complete excision of the segment of bowel containing the growth together with its lymph-bearing area, and followed by immediate restoration of the continuity of the bowel. Apart from consideration of questions of a general or constitutional nature, this ideal treatment may be contraindicated by (1) secondary deposits in the liver; (2) metastatic peritoneal deposits—especially likely to occur in the pouch of Douglas; (3) glandular involvement beyond the limits of practicable surgical removal, and (4) local extension and fixity. Of these, the first and second are, of course, absolute contraindications

to radical operation, but with regard to glandular enlargement it must be remembered that this is not necessarily of a secondary malignant character, but may be of an inflammatory nature only, due to associated sepsis. Local fixity, moreover, rarely prevents radical measures, since by free division of the peritoneum along the outer border of the colon, many growths which at first sight appear too fixed may be rendered sufficiently mobile for excision. If a radical operation be definitely contraindicated then a "short-circuit" (that is, lateral anastomosis) should be performed, provided there is a sufficient length of colon below the growth to permit of approximation to the distended bowel above without undue tension. Only when a "short-circuit" is quite impossible must we, as a last resort and to prevent future intestinal obstruction, fall back on colostomy proximal to the growth.

Many cases, however, are already associated with intestinal obstruction when first seen, and it is imperative that this be relieved before any radical extirpation with restoration of the continuity of the bowel be attempted, since it is the universal experience of surgeons that resection of the colon in the presence of obstruction is a very unsafe procedure—the congested and oedematous wall of the bowel failing to hold the sutures properly, so that leakage at the suture line is very probable. In such cases the best course, I believe, is to perform caecostomy under nitrous oxide or local anaesthesia: only when, by this means, complete relief of the obstruction has been attained must recourse be had to exploratory laparotomy with a view to radical removal of the growth and restoration of the continuity of the bowel. If after this has been accomplished the caecostomy does not close spontaneously, a slight plastic operation will suffice for its obliteration.

CANCER OF THE RECTUM.

It is an extremely unfortunate fact that at the present time fully 75 per cent. of the cases coming to our hospitals with cancer of the rectum have already reached a stage much too advanced for any hope of radical operation. This is surprising when it is remembered that such growths are readily available to rectal palpation, and it is largely the neglect to make a digital examination of the rectum whenever patients come complaining of rectal symptoms that is responsible for this lamentable state of affairs. Even when blood has been passed per anum it is not uncommonly too readily assumed that it is due to the commonest cause—piles—without a digital examination.

Symptoms.

The early symptoms of rectal cancer are often indefinite, and are essentially those already described for growth of the colon. A patient whose bowels have previously acted regularly, on going to morning stool and thinking to have a normal motion, finds instead that he passes mostly blood-stained mucus and flatus, and that he has to repeat his visit very shortly, possibly for several times, before he obtains relief. This "spurious diarrhoea" is really indicative of constipation. Severe bleeding from the rectum is uncommon except in an advanced stage, but occasionally it may be an early symptom, and then, fortunately, alarms the patient and leads him to seek advice in an early and operable stage. Pain is often completely absent in the early stages; if present it may be felt in the rectum, in the sacrum, or over the lower abdomen. An alteration in the shape of the faeces, chiefly in the direction of flattening, is sometimes noticed early, especially in the stenosing type of growth and when situated near to the anus; with a high growth the faeces may be remoulded in the rectum after passing through the stricture and thus appear of normal shape.

Diagnosis and Treatment.

Suspicion of rectal trouble having been aroused, a digital examination should be made forthwith, and should it prove negative a sigmoidoscopic examination should follow, since the commonest site of growth is the recto-sigmoid junction, and this may not be reached by the examining finger. Bimanual examination with the forefinger of one hand in the rectum and the other hand flat on the lower abdomen sometimes enables an otherwise impalpable growth to be discovered. By digital examination is determined, not only the presence of a growth in the rectum, but also the extent to which it has already involved the adjacent structures—prostate, bladder, vagina, uterus, and sacrum. If not fixed to any of these, and if no enlargement of the liver can be felt (or of the inguinal glands in cancers involving the anal canal), then the question of a radical operation must be considered. The possibility of this cannot be finally determined until, as the first operative step, the abdomen has been opened and the presence of metastasis in the liver or peritoneum, or the too extensive involvement of lymphatic glands, definitely excluded. It has, unfortunately, been my experience on more than one occasion to find that with a comparatively small and freely mobile rectal growth—and presumably, therefore, an early one—a secondary deposit in the liver has been disclosed on opening the abdomen, and the contemplated radical operation thereby prevented. We need not to-day enter into the much discussed question of the relative merits of the two chief radical operative procedures at present in vogue: (1) the abdomino-perineal operation perfected by Miles, and (2) perineal excision following a preliminary colostomy; they both entail a permanent iliac anus as part of the price the patient is called upon to pay for any hope of cure of a rectal cancer. Possibly, in the future, with cases presenting themselves at an earlier stage and with a better selection of cases, it may be feasible to remove the rectum with preservation of the sphincters and restoration of the continuity of the bowel, but at present such is not to be recommended.

If a radical operation be deemed impracticable, either because of the local extent and fixity of the primary growth or because of the presence of metastases, then the question of a palliative colostomy has to be considered. This should certainly be performed wherever there is any evidence of actual or of shortly threatened obstruction, and considerable relief may be expected therefrom. In the ulcerative types of growth obstruction is not a marked feature, and the patient's chief distress is occasioned by the profuse discharge of blood and muco-pus from the growth, necessitating the passage of very frequent stools; although by diverting the faeces from the growth colostomy may be reasonably expected to diminish the amount of this discharge, yet sufficient may remain to cause patients to express disappointment at the small measure of relief afforded them by the operation, and this should be fully explained to them before their consent to colostomy is obtained.

THE THYROID GLAND IN THE FULL-TIME HUMAN FOETUS AND IN THE NEWLY BORN INFANT.

(*With Special Plate.*)

BY

IAN MURRAY, M.D.,

DISPENSARY PHYSICIAN, VICTORIA INFIRMARY, GLASGOW.

(From the Institute of Physiology, University of Glasgow.)

INTRODUCTION.

VARIOUS descriptions have been given of the appearance of the thyroid gland of the human subject about the time of birth. The majority of workers have recorded a condition very different from that seen in the normal adult gland, and several have advanced hypotheses to explain it.

It would seem that typical colloid appears at some period of intrauterine life. Elkes (1904) described it in foetuses from 4½ to 6½ months, Livini (1922) in embryos of 62 to 66 mm., while Müller, Peremeschko, and Brechat, cited by Méroz-Tydman (1910), found it present, the first in a foetus of 5 months, the others at a later period. Wölfer (1880), however, was of the opinion that colloid formation did not commence until the end of foetal life or even till after birth. Treating this investigation from the chemical standpoint, Marine (1922) states that the iodine content of the thyroid increases with the increasing age of the foetus. Fenger

(1913, 1915) examined the iodine content of a large series of foetal cattle, pigs, sheep, and man, and came to the same conclusion.

Immediately after birth, according to some observers, a very striking change in the histological appearance of the thyroid occurs. Zielinska (1894) found solid collections of cells filling the vesicles without any sign of colloid. Elkes gave a similar description, and emphasized the difference between the foetal gland and that of the newly born.

Méroz-Tydman examined a series of thyroids from still-born and newly born children, and found that in both some glands were made up of elongated or rounded heaps of epithelial cells closely pressed together, while others showed vesicles with desquamating cells and no colloid; others again were composed of almost normal-looking vesicles containing a little colloid, in which, however, were so many vacuoles that it had the appearance of a thin network. Hesselberg (1910) considered that the normal appearance of the thyroid, at least during the first week of life, is one of empty vesicles and desquamating cells.

Maurer, cited by Hesselberg, on the other hand, found that after birth colloid is sometimes present. Elkes drew his conclusion, that the thyroid at this age is colloid-free, from the examination of a series of thyroids from newly *born children. There was one exception, however, which* showed well differentiated vesicles filled with colloid. Garnier (1899) found no great difference between the thyroid of the newly born and that of the full-time foetus. Hesselberg also was doubtful if there was any marked difference, as she found, in three out of nine foetuses from 7 to 9 months, the desquamated condition of the gland, which she considered the normal appearance in the newly born. Cooper (1925) stated that during the first two weeks after birth the thyroid shows little difference from that of the full-time foetus, but that practically all the vesicles are empty.

Four theories as to the cause of this change in the thyroid after birth have been suggested. Wölfer, after examining a series of glands from feeble and stillborn children, and finding that they had few or no vesicles and no colloid, considered that, as this condition resembled the state of the thyroid before colloid formation was begun, the cause of the appearance after birth was arrested development of the gland.

De Quervain (1904) suggested that the desquamation of the epithelial cells might be due to disease in the child. Perrando, cited by Hesselberg, and Elkes found a similar condition in thyroids taken from children who had suffered from congenital syphilis. Garnier, in the course of an investigation on the effects of infectious diseases of the thyroid gland, found, however, that desquamation was present in the thyroid of a stillborn child, otherwise normal, after a prolonged labour.

Elkes was of the opinion that some metabolic change, taking place immediately after birth, might account for the alteration in the thyroid. Hesselberg, however, found no evidence of desquamation in the glands of various animals killed and examined shortly after birth, and disagreed with Elkes's theory, thinking that as some similar metabolic change probably occurs in the lower animals this should, if the hypothesis were correct, cause some alteration in their thyroids also.

Hesselberg held the view that the disappearance of colloid and the desquamation of the epithelial cells was due to damage to the thyroid during birth, by reason of the relative narrowness of the human birth canal. She holds that this theory would explain Garnier's results mentioned above.

Present Investigation.

The present investigation was undertaken with a view to determining whether the condition of the thyroid at birth might be related in any way to the state of development of the child, or whether it might be due to autolysis or *post-mortem* degeneration. Neither of these possibilities has apparently been inquired into, as no reference to either has been discovered in the literature. To obtain some idea of the effects of autolysis on the thyroid gland before examining the human thyroids described later, observations were made on the *post-mortem* changes in the thyroid of the dog.

A. Study of the Degenerative Process in the Thyroid.

Seven experiments were carried out with a view to discovering the effect of autolysis in the thyroid. Cruickshank (1911) carried out similar experiments with liver and kidney, and his method was followed. After trying various media he found that he obtained the best results by keeping the tissue in a moist chamber, and in several of his experiments he was successful in obtaining autolysis similar to that seen in the body and in foetal tissues.

Previous to the removal of the thyroid a sterile Petri dish was prepared in the foot of which was a layer of blotting paper soaked in salt solution, both paper and solution having been sterilized. The neck of the dog was then shaved and washed carefully—no antiseptic could be used as autolysis is retarded by its presence. The two thyroids were removed and transferred as quickly as possible with sterile instruments to the Petri dish. Each thyroid was then cut with a sharp knife into four parts. One part was removed and fixed at once in formalin as a control, and the dish was closed. In some cases the Petri dish was kept at room temperature—to compare with the rate of change in the thyroid of a foetus kept in the mortuary—and in others it was placed in an incubator kept at a constant heat of 37°. At intervals of twenty-four hours a piece was removed and fixed. The tissues were prepared by the usual paraffin method, cut, and stained with haemalum and eosin. The greatest care was taken to maintain sterility, but it is doubtful if this was successful, and it certainly failed in some cases which showed bacterial growth round the margins. Cruickshank also experienced very great difficulty in keeping the organs sterile, and bacteriological examination proved that in about half his experiments all his precautions had been of little avail.

Results.

In the case of the thyroids at room temperature the degenerative process took place gradually throughout the week, the duration of the experiment. The first change was the appearance of vacuoles round the margin of the colloid masses in the vesicles, which had shrunk somewhat. At this stage the vesicular cells are still cubical and ranged regularly round the vesicle. This condition is illustrated in Fig. 2, which shows such a thyroid forty-eight hours after removal. Fig. 1 shows the state of the gland immediately after removal from the body.

The lining cells of the vesicles next become detached from the basal membrane and all the colloid disappears. As the process of degeneration progresses the cells become separated from each other and lie free in the lumen. As this proceeds the section takes on a much more cellular appearance. The vesicles become small, and less and less distinct until their outline, marked by a thin strand of connective tissue, can only with difficulty be made out. The interior of the vesicles is ultimately packed with epithelial cells, many of which appear as large rounded [illegible] with a dark nucleus. The thyroid shown this state. It was fixed seven days after removal, during which time it had been kept at room temperature.

The rate of degenerative change in the thyroids kept in the incubator at 37° was about three times that of those kept at room temperature. The same process was observed, but the change at the end of twenty-four hours was greater than that in those kept in the cooler temperature for forty-eight hours. In the specimens kept in the incubator further changes than those described above were observed. Gradually the cells and nuclei degenerated until the section presented an almost homogeneous pink appearance. For the present purposes, however, only the changes described and illustrated above are of interest.

There is one other point to which attention may be directed. Fig. 1 shows a perfectly normal thyroid of a dog with large well filled vesicles, while in Fig. 2 the same thyroid is shown after forty-eight hours' degeneration. In the latter vacuoles are very noticeable, although there are none present in the freshly fixed gland. It would appear that these vacuoles resulted from a process of degeneration, and this is confirmed by the work described below on the thyroid of the foetus.

Many views have been expressed as to the cause of the appearance of the vacuoles which were frequently observed in the colloid. Cowdry (1922) and others have ascribed them to shrinkage of the colloid in preparation. Jackson

(1916) believed they were connected in some way with the process of colloid formation, while Cooper (1925) has advanced the opinion that they may be due to absorption of colloid into the circulation. Neither of the last two theories, however, could account for the occurrence of vacuoles *post mortem*, and if Cowdry's hypothesis applies here, it would seem, as there was no shrinkage in the freshly fixed gland, that there must be some chemical change in the colloid substance before this can occur.

B. *Examination of a Series of Young Human Thyroids.*

At the Glasgow Royal Maternity Hospital routine *post-mortem* examinations are performed on all infant corpses, whether the child has been stillborn or has lived. Full details as to size and development, as also to the *post-mortem* findings in the various organs, are recorded. Through the kindness of Dr. Norman Cruickshank I was permitted to examine the thyroid from 70 of these cases.

The gland was fixed in formalin after removal and weighing, and was embedded by the paraffin method, cut, and stained with haemalum and eosin.

Details as full as possible were obtained in each case, special note being taken of the state of development, as it was intended to correlate this, if possible, with the histological findings in the thyroid. The age of the foetus was calculated from the date of the last menstruation to the date of birth. The former, however, was often difficult to ascertain, and many of the ages thus obtained were only approximate. Accordingly no great reliance can be placed on this. A much more accurate idea of the state of development can be obtained by examination of the condition of the various centres of ossification. For this purpose the following were noted: the number of centres present in the mesosternum, and the size of the centres in the astragalus, the os calcis, the lower end of the femur, and the upper end of the tibia. The weight, length, and sex of the child, and the number of the pregnancy, were also noted.

As the possibility had to be taken into account of the appearances of the thyroid being due in some cases to autolytic change, the time from death or stillbirth until the time of *post-mortem* examination was noted. This could be obtained accurately in the case of children who had lived, but in the others it was very difficult, and usually impossible, to find out how long the foetus might have been dead *in utero*. As the majority of craniotomies were performed on account of contracted pelvis, and as in many such cases the child is alive until the operation is undertaken, it was thought that a more accurate estimate of the time that the child had been dead before examination might be obtained in the instances where this was done than in the other stillbirths, and these cases were consequently segregated. There cannot, of course, be the same exactitude as when the child had lived, but probably more than with the remaining stillbirths.

I am indebted to a house-surgeon for three thyroids which he removed and fixed immediately after delivery. In these cases craniotomy was performed on living foetuses, the mothers' pelves being greatly contracted. The glands obtained thus were therefore free from any suspicion of *post-mortem* change.

Histological Examination.

The appearances found in the thyroids were very varied. Some were made up of colloid-containing vesicles, some of empty vesicles, while others presented a solid cellular appearance quite unlike that normally associated with this gland. In this description they may conveniently be grouped into two classes—those containing colloid and those free of colloid.

1. *Glands containing Colloid.*—Into this class fall 22 of the thyroids examined. The gland was composed of vesicles lined with cubical epithelium and filled with colloid which stained well. Some showed a certain amount of intervesicular tissue, but where the vesicles are small this is only to be expected as the result of the section passing tangentially through the walls of some vesicles. The vesicles varied in size, but were always much smaller than in the adult gland. Fig. 4 shows the low-power view, and Fig. 5 the appearance, seen under high power, of the sections of the thyroids which were fixed immediately after death. These are more or less typical of all the glands included in this group, although some showed more colloid. They were selected for illustration as there can be no doubt about their freshness. There was little difficulty in separating this group from the next, as the presence of the colloid was in every case noticeable at a glance. As regards vascularity, it was found that in some thyroids the capillaries were congested, while in others they were more or less empty. It seems possible that the congestion described by some observers as being invariably present may be due to the character of the labour.

2. *Glands containing no Colloid.*—As has been indicated, these thyroids varied from a condition in which there was merely an absence of colloid to a state in which vesicles as such could scarcely be recognized. For descriptive purposes, however, they may be divided into three types:

A. In a few thyroids there are still traces of colloid in the vesicles. This, however, stained faintly and contained large vacuoles, which were often so numerous that all that remained of colloid was a thin network between these vacuoles. The walls were lined with cubical cells more or less regularly arranged, though here and there they had become detached and were escaping into the lumen (Fig. 6).

B. Many of the sections presented a characteristic clear appearance. The glands contained no colloid and the protoplasm of the cells stained rather faintly. Vesicles were clearly discernible, but many of the cells composing their walls had separated from the basal membrane. When they still retained their attachment they were of more columnar shape (Fig. 7).

C. A considerable number of the thyroids had a very cellular appearance. In many cases it was only with difficulty that the outline of vesicles could be distinguished, marked out by a thin line of connective tissue cells. The vesicles were filled with desquamated cells of more or less rounded shape (Fig. 8). As in the thyroids of type B, the protoplasm of the cells stained more faintly than in those glands which contained colloid, while the nuclei were much darker. In this group, as in the first, some glands were very congested, while in others there were few blood cells visible.

For brevity of description, in the accompanying table the thyroids have been classed in three groups: Group I is made up of the thyroids containing colloid; those colloid-free glands described above as types A and B are collected together into Group II; while the remainder (type C) form Group III.

Summary of Results.

A. *Children who Lived.*—Sixteen of the thyroid glands examined were taken from children who had survived for some time after birth. This time varied from a few hours to ten days. Of these, 8 were found to be of the type described above as Group I, 5 of Group II, and 3 of Group III. Comparison of the data collected about each case showed great variation in the age, weight and length, state of ossification, duration of life, of the infants whose thyroids were classed together in one group. Moreover, similar variation occurred in all three groups. One fact, however, may be observed—namely, that in every case in which colloid was found to be present the *post-mortem* examination had been carried out within twenty-four hours of death, whereas in the others with only one exception this was delayed for two or three days.

B. *Stillbirths: Craniotomies.*—In this class, while similar variations were found in the age and development,

Class.	No. of Thyroids Examined.	Type of Thyroid.	No. of Days from Time of Death until Time of *Post-mortem* Examination.	
			Average.	Standard Deviation.
A. Children who lived.	8	Group I	0.75	0.250
	5	Group II	2.00	0.633
	3	Group III	2.33	0.481
B. Stillbirths—craniotomies	6	Group I	0.63	0.567
	3	Group II	1.66	0.494
	5	Group III	3.80	0.400
C. Remaining stillbirths.	8	Group I	1.18	0.493
	6	Group II	1.33	0.471
	26	Group III	2.38	0.836
Totals.	22	Group I	0.87	0.427
	14	Group II	1.64	0.534
	34	Group III	2.58	0.741

it was also noted that the six thyroids belonging to Group I were taken from infants on whom the *post-mortem* examination had been performed within twenty-four hours of delivery. In three cases where the thyroid showed desquamation of the epithelial cells and no colloid (Group II) the necropsy had taken place from one to two days after delivery, and in five, in which this was delayed for three or four days, all the glands showed vesicles filled with desquamated cells (Group III).

C. *Remaining Stillbirths.*—In 8 cases the thyroid showed the appearances of the Group I type. On 6 of these the *post-mortem* examination was performed within twenty-four hours, and on the other 2 within two days. In the case of the 6 thyroids which belonged to Group II the necropsy was carried out from one to two days after birth, while with those of Group III this varied from one to four days. As with the other two classes, great variation occurred in the other factors considered, with none of which could the thyroid appearances be correlated.

These results are summarized in the accompanying table. The cases are arranged according to the histological appearances of the thyroid, and for each group the average number of days from death or stillbirth until the time of the *post-mortem* examination is given, together with the standard deviation. It will be seen that in each section this time is shortest in the case of the Group I thyroids, and longest with those of Group III. This is very apparent when the averages for all the thyroids of each group are totalled. In the cases where the gland was of the Group I type the autopsy was performed 0.87 day after death or stillbirth, while with Group II this was 1.64 days, and with Group III 2.58 days.

Thus it appears that these striking variations in the histology of the thyroid cannot be due to variations in development, whether reckoned by age, weight and length, or extent of ossification. Neither do they seem to be related to the sex of the child, or to the number of the pregnancy. Thus one has to consider whether these variations may be accounted for by the differences in the time between the death of the child and the fixation of the thyroid—that is to say, whether they can be due simply to degenerative changes.

The thyroids from the three cases of craniotomy in which the glands were fixed within a very short time of death all present a similar appearance, and all show a considerable amount of colloid—that is, they belong to the type described as Group I. No degeneration can have taken place, and consequently these may be looked on as normal, although, as already stated, they do not conform exactly to the appearance found in the adult gland. Taking this standard as normal, it will be seen that in all cases in which the gland was fixed within twenty-four hours of death the thyroid may be regarded as normal, while in practically every case in which it remained in the body for a longer period it may be said to be abnormal. The exceptions to this are: (1) a few cases where the normal appearance was found in thyroids removed two days after death, and (2) seven of the cases of stillbirth other than craniotomies (Class C) where the gland belonged to Group II or Group III. The latter may be accounted for by the fact that from the clinical notes in these cases no estimate could be formed as to how long the child may have been dead *in utero*. As has been seen from the experimental work already described, autolytic change takes place at a greater rate at blood temperature than at room temperature. Thus if the child were dead *in utero* for a comparatively short time it is highly probable that by the end of twenty-four hours after delivery any degenerative change would be very much more advanced than if the child had lived till the time of birth. This, then, may be the reason for the colloid-free condition appearing so early in these cases. In practically all cases in which the necropsy was performed two days after birth, as also in all cases where this was done at a later date, the thyroid presents this abnormal condition.

To sum up, it will be seen that the type of thyroid described as being of Group I, which appears only when the gland had been fixed within a short time of death, is to be considered the normal histological structure of the thyroid at the time of birth. Group II and Group III thyroids are to be looked on as abnormal, and it will be seen that the appearances of these types of thyroid resemble those described as occurring in the degenerating thyroid of the dog. Taking this together with the finding that these types were seen when the gland had not been fixed until later than those of Group I, we may conclude that Group II represents a degenerative change in the thyroid, and Group III that change still farther advanced.

Further evidence that the colloid state is normal at the time of birth, and that desquamation is abnormal, is obtained by examination of the thyroid of experimental animals. As already mentioned, Hesselberg found that the thyroid in dogs, cats, and rabbits immediately after birth were well filled with colloid and showed no sign of the desquamation, which she considered to be normally present in the thyroid of the child during the first three weeks of life. I have on several occasions examined the thyroid of full-time guinea-pigs removed by Caesarean section, and have invariably found a similar condition.

Hesselberg sought to explain the difference in the thyroid at birth in man and in animals, in that that of the former showed desquamation and the latter did not, by suggesting that, owing to the narrow birth canal in the human subject, the thyroid was injured during delivery. If this were so we would expect to find desquamation more frequently in a first-born child, and not so often in the children of a multipara, when the birth is usually easier; but this is not borne out by this work. Moreover, a large proportion of stillbirths are due to difficult labour, yet a considerable number of such in this series had normal thyroids. Garnier found that after a prolonged labour the child's thyroid showed desquamation. In such a case, however, it would seem that there was every possibility of the child being dead *in utero* for some considerable time, in which case autolysis would account for the change he described.

Conclusions.

1. The thyroid gland of the full-time human foetus, and also of the newly born infant, appears to be composed normally of small vesicles lined with cubical epithelium and filled with colloid which stains well. The glands may or may not be congested.

2. When variations from this conception of the normal are observed it seems probable that they may in many cases be due to *post-mortem* degeneration.

3. The changes which occur in the thyroid gland *post mortem* may be summarized thus. First, vacuoles appear in the colloid which ultimately disappear completely. The epithelial cells then become separated from the basal membrane. Eventually the vesicles become filled with desquamated cells and the gland presents a solid cellular appearance.

4. As the formation of vacuoles in the colloid may take place after death, these cannot always be regarded as evidence of activity on the part of the thyroid.

5. No relationship was found to exist between the condition of the thyroid in the full-time foetus and the development of the child as reckoned by the extent of ossification.

This work was commenced during the tenure of a Carnegie Research Scholarship, and was carried out in the Institute of Physiology, at the University of Glasgow. I wish to thank Professor D. Noël Paton for kind help with, and interest in, the work, and Dr. Norman Cruickshank for permission to use the records of the Pathology Department of the Royal Maternity Hospital. I am greatly indebted to Mr. John Bell for the care which he took in the preparation of the photographs.

THE SURGICAL TREATMENT OF PHTHISIS AND BRONCHIECTASIS.*

(With Special Plate.)

BY

A. TUDOR EDWARDS, M.D., M.CH.CANTAB., F.R.C.S.ENG.,

SURGEON TO THE BROMPTON HOSPITAL; SENIOR ASSISTANT SURGEON, WESTMINSTER HOSPITAL.

IN most European countries, and to an increasing extent in America, operative treatment of certain classes of cases of phthisis and bronchiectasis has been widely accepted. In this country—chiefly, in my opinion, as a result of lack of knowledge of the results obtainable and of the more suitable types to submit to operation—progress has been very slow. Operative mortality has been very considerably reduced; and whereas formerly it has been so high that only the most hopeless cases were submitted to operation, a stage has now been reached where operation can be recommended with reasonable certainty that the immediate post-operative period will be safely passed.

The two conditions—bronchiectasis and phthisis—offer very many similarities, and as their cure is dependent in many instances upon the same factors I shall consider them together, pointing out various minor differences as occasion offers. In both diseases the evolution of surgical treatment has developed along similar lines. Both diseases occur at a comparatively early period in life and both have a very high mortality. In third-stage tuberculosis the mortality is probably in the neighbourhood of 80 per cent. in the course of five years, and Powell and Hartley state that "bronchiectasis, owing to its anatomical character, is not a disease from which we may expect recovery. At the best, all that we may hope for is that, by preventing decomposition of the sputum, we may be able to arrest its further progress. In nearly all cases, in spite of treatment, the disease gradually advances."

The object of the surgeon is to prevent the evil results of the contraction of fibrous tissue on the important pulmonary structures, either by allowing the rigid thoracic wall to fall in, or, by interposition of either solid or gaseous buffers between the chest wall and lung, to allow localized or generalized pulmonary collapse. In this way cavity walls are brought into apposition and healing is aided, in addition to which the lung is given adequate rest.

METHODS OF TREATMENT.

Division of Adhesions.

These operations are used in cases where artificial pneumothorax treatment is only partially successful owing to the presence of localized adhesions between parietal and visceral pleurae, which prevent full pulmonary collapse. Only comparatively narrow bands offer any hope of successful division. These bands are commonly found overlying cavities in the lung; their deleterious effects are shown by the figures of Sangman and Gravesen. In 211 pneumothorax cases the proportion of patients able to work after three to thirteen years was only one-half as many in those with adhesions as compared with those free from adhesions. Open thoracotomy with ligature and division of the adhesions has been tried, and resulted in some cases in widespread infection of the pleura or eventual intractable fistula. It has therefore been abandoned. The method of choice is the cauterization of adhesions under the control of thoracoscopic vision, as devised by Jacobaeus of Stockholm.

The operation, performed under local anaesthesia, consists in the introduction of a trocar and cannula through a convenient intercostal space, the telescope with its terminal light replacing the trocar. After perforation of the pleura any adhesions present are examined with a view to their division. If this is considered possible, a finer trocar and cannula is introduced in such a position as to bring the cautery as nearly as possible at right angles to the adhesions to be divided. The current required to cause a strong red glow in the cautery is estimated before introduction and is controlled, advisably, by a foot switch. Gentle pressure will result in gradual division of the adhesion. When this is complete the ends retract and should be examined for any bleeding points, which, if present, can be retouched.

When doubt exists as to the presence of a prolongation of a cavity into the pulmonary end of the adhesion cauterization should be done as near the parietal pleura as possible. Smoke may temporarily obscure the field, but is rarely a serious inconvenience. A slight degree of surgical emphysema is a common sequel, but the main complication has been severe empyema, either early or late, and has resulted in death in 7 to 8 per cent. of cases. A small effusion, the result of irritation, is fairly common, but reabsorbs in the majority of cases within a short time. One case of fatal haemorrhage has been recorded.

The indications for this procedure depend upon *x*-ray appearances in conjunction with the amount and character of the sputum, the temperature, and the pulse. Thus, during artificial pneumothorax treatment, when a definite cavity is held uncollapsed by a fine adhesion, and the temperature, pulse rate, and sputum are increased, the operation is advisable. The operation should not be attempted in the presence of pleurisy nor with bands of greater thickness than one centimetre. Within these limits this auxiliary method of treatment appears to have a limited but definite field of usefulness in tuberculosis.

In my series of fifteen patients thoracoscoped with a view to cauterization the complete operation was only possible in four, of whom two have done well eventually.

Pneumolysis.

The object of this operation is to produce a localized collapse of the lung in order to compress cavities. The operation consists in the separation of the lung, with the visceral and parietal pleurae (being adherent), from the chest wall, the line of cleavage being underneath the endothoracic fascia. It may be performed anteriorly, in the axilla, or posteriorly. The latter site is usually chosen where the operation is combined with thoracoplasty. Various media have been used for filling this space between pleura and chest wall. Tuffier uses fat from the abdominal wall, lipomata, or omentum. Baer uses paraffin wax with a small proportion of bismuth carbonate and iodoform. The objection to this fill is that it acts as a foreign body, and may be discharged following sinus formation. Archibald has used a portion of the pectoral muscle, and Sauerbruch occasionally uses a gauze pack, repacking the space repeatedly, with the result that granulation tissue is formed over which the superficial structures are subsequently allowed to fall in.

Pneumolysis may be used as an independent or a supplementary procedure. In the former case results have been disappointing, the reasons being that the procedure is too localized. Tuberculosis is very rarely localized to the apex of the lung, and for bronchiectasis enormous fills would be required to bring about any noteworthy compression of the base. As a supplementary operation to pneumothorax some quite satisfactory results have been recorded. The best results have been obtained in apicolysis secondary to thoracoplasty, in which a residual cavity has remained at the apex.

I have operated on two cases by this method—one in order to collapse the apical portion of the lung, following incomplete artificial pneumothorax, the other as supplementary to a previous thoracoplasty with a partially collapsed apical cavity. In each case fat was used as the filling medium, and both cases healed by first intention. The ultimate benefit, however, was only slight, and it is doubtful if the operation justifies a wider field.

Phrenicotomy.

Paralysis of the diaphragm resulting from division of the phrenic nerve will cause diminution of the hemithorax and consequent collapse of cavities in the base of the lung, and even some decrease in size of cavities higher in the lung. Simple division of the phrenic nerve in the neck, however, is not always followed by diaphragmatic paralysis, complete and permanent. This is due to the presence of accessory phrenic fibres which join the main

* Abstract of a Hunterian Lecture delivered at the Royal College of Surgeons of England.

stem after its entrance into the thorax. When present, they join the main phrenic in the thorax within two inches of the clavicle, and are stated to occur in from 30 to 40 per cent. of cases. The original operation of simple division has therefore been modified.

Radical Phrenicotomy (Local Anaesthesia).—A small incision is made parallel with the posterior border of the sterno-mastoid muscle in its lower half. The fascia is incised and the muscle drawn forwards. The phrenic nerve is exposed beneath the fascia overlying the scalenus anticus. The nerve is anaesthetized, divided, and the lower end seized in artery forceps. The nerve, carefully freed from surrounding structures, is slowly twisted around the forceps, and gradually withdrawn from the thorax. Often the nerve can be completely extracted, in other cases it may require division when a sufficient portion is withdrawn. Some dragging pain in the chest is common, and spasmodic movement of the diaphragm may occur. The only noteworthy complication has been haemorrhage, from which death has been reported in one case out of several hundred recorded. The average raising of the diaphragm after operation was stated by Felix to be 7 cm. at the end of inspiration and 3 cm. at the end of expiration, and it is said that the lung volume is reduced by 400 to 800 c.cm. The indication for this operation in tuberculosis is when the disease is subacute and the patient too ill for major proceedings, or when the disease in the better lung appears too extensive for artificial pneumothorax treatment. It can be used as an indication of the condition of the so-called "better lung" preliminary to thoracoplasty. When basal adhesions limit the value of pneumothorax treatment it is of value, and has been advised as a routine to prevent mediastinal displacement and reopening of cavities after pneumothorax treatment has been concluded. In bronchiectasis great improvement has followed radical phrenicotomy, but the cure is rarely complete. It has also proved valuable in haemoptysis in this disease.

My series of cases numbers 17, 5 being supplementary to thoracoplasty, 3 to pneumothorax treatment. In 8 of these simple division of the phrenic nerve was performed, and in those cases in which no other operation was done proved disappointing. The last 9 cases, however, have had radical phrenicotomy performed, and the results have proved much more satisfactory. (Since the above I have carried out the operation a further thirty times, making a total of 47 cases, without complication and in practically every case some definite improvement.) The diaphragm has become raised in every case and the chest capacity has been obviously reduced, with improvement of symptoms.

Thoracoplasty.

The following are the indications for thoracoplasty in tuberculosis: fibrotic disease with mediastinal displacement; cases in which artificial pneumothorax has been successfully carried out but in which reactivation results when the treatment is given up (in these cases pleural adhesions generally prevent further pneumothorax treatment); certain cases of long-standing disease with more extensive cavitation; pleural effusions, recurrent in spite of other treatment; true tuberculous empyemata, unassociated with secondary infection; recurrent haemoptysis resistant to other forms of treatment. The important factor in all cases is that the disease must be mainly unilateral. There should be no signs of recent activity in the "better" lung unless they are minimal and considered to be the result of spread from the worse lung. Cavitation in the better lung negatives operation. In general, there should have been no spread of disease in the better lung as shown by physical signs or x-ray examination during the three months preceding operation.

Thoracoplasty is, as a general rule, inadvisable under 14 years of age, as in the contracting fibrotic type of disease the chest wall naturally tends to fall in. In adults over 45 years of age the cardiac condition is not so satisfactory and the chest wall and costal cartilages are rigid. The general condition must be taken into consideration, although wasting is not a contraindication in itself. Advanced lesions of the cardio-vascular system will contraindicate except where cardiac embarrassment is due to mediastinal displacement. Moderate laryngeal lesions are permissible, but tuberculous lesions in other parts—especially intestine, kidneys, and bones and joints—are generally accepted as contraindications.

In bronchiectasis it has not yet been definitely determined which are the types of disease to give the best results from thoracoplasty, but the disease must be unilateral. Physical signs are often absent or indefinite even in advanced disease, and x-ray evidence may be very doubtful. The introduction of substances opaque to x rays—such as lipiodol, an oily solution of iodine—into the bronchi has proved of very great value and will generally show whether the disease is unilateral or bilateral. The substance is introduced into the trachea under local anaesthesia; the patient is tilted to the side required, and the chest x-rayed about ten minutes later. The two lungs are examined in this manner at seven days' interval.

Partial thoracoplasty, done either in the upper or lower part of the chest in combination with artificial pneumothorax or as a sole method, has proved unsatisfactory in the majority of cases, being too localized and preventing the full value of the rest factor.

The Operation of Thoracoplasty.

Apart from my first eight cases, which were done under local anaesthesia alone, all thoracoplasties have been done under the combination of gas and oxygen with local anaesthesia. The usual antishock treatment with glucose saline is undertaken for forty-eight hours. One hour before operation the patient is urged to empty the cavities of all secretions by coughing and changes of posture.

In my own series the two-stage operation has been done as a routine, owing to diminution in shock and to the lessened absorption of toxins into the circulation from the more gradual compression of the lung. The interval between the stages is as near as possible three weeks.

The operation itself is performed with the patient in the semi-sitting posture, the vertebral column being made convex towards the affected side by means of an axillary cushion. The incision commences from the level of the spine of the scapula and passes downwards in the space between the scapula and the vertebral column, turning outwards along the tenth rib, to the posterior axillary line. The muscles are divided in the same line, and the skin edges clipped off with towels. The ribs are exposed by raising the scapula, and each intercostal nerve from the eleventh to the fourth infiltrated with a few cubic centimetres of 1 per cent. novocain. The periosteum is rapidly stripped off each rib and the small back muscles off the posterior ends. The ribs from the eleventh to the fifth are then divided posteriorly as near the transverse processes as possible and anteriorly as far as is required for each individual rib. This is variable, but generally about 4½ to 5 inches is removed from the fifth to the tenth and only a small portion of the eleventh. The wound is closed in layers with drainage for twenty-four to twenty-eight hours and firm strapping applied over the dressing to fix the involved hemithorax, but allowing the tube to be withdrawn without disturbing the main dressing. The main point in after-treatment is the insistence on the expectoration of sputum. Pain can be prevented by omnopon, and coughing assisted by firm hand pressure on the affected side during the effort. Sputum rapidly increases in quantity after the first three days, diminishing later. The temperature and pulse rates reach their maximum on the third day, owing probably to some retention of sputum and to increasing absorption into the circulation from the collapsing lung.

The second stage, comprising removal of portions of the first four ribs, is performed through an incision from the upper trapezius and following the inner border of the scapula to its inferior angle. The further steps are similar to the first operation, the first rib only offering difficulty. It is often advisable to complete the removal of the second rib before any attempt is made to expose the first. Only half an inch need be removed, but care must be taken not to damage the dome of the pleura, or the vascular and nervous structures in the near neighbourhood.

The after-treatment is similar to that of the first stage. A compression splint is worn, after the wound has healed,

for several months until the bone union is firm. Sanatorium treatment is advisable for several months after operation, especially for tuberculosis.

The complications are: death from shock; death from pulmonary embolus; aspiration pneumonia of the better lung, the most common complication leading to early death; infection in the wound arising from spread through the pleura; later deaths generally resulting from spread of the disease in the sound lung; one fatal case of haemorrhage has been recorded from erosion of the subclavian artery by the first rib (Brunner).

Alexander has collected all the results of thoracoplasties for tuberculosis published in the period 1918 to 1925. There were 1,159 operations, by fifty-three surgeons, and 57 per cent. of the patients showed improvement or were cured. All these were far advanced and were becoming worse in spite of sanatorium methods of treatment. So far I have done the operation of thoracoplasty on 33 patients. Of these, 33 per cent. have been apparently cured or greatly improved; 21 per cent. have improved; in 20 per cent. there has been slight or no change; 20 per cent. have died later from tuberculosis; and 6 per cent. have died within three weeks of the date of operation.

ILLUSTRATIVE CASES.

CASE I.—*Tuberculosis.*

A woman, aged 31, with a history of having had pleurisy in 1918 and again in 1921. Under Dr. Vere Pearson at Mundesley Sanatorium artificial pneumothorax was started on the right side and continued for eighteen months. It was abandoned owing to pain and contraction of the pneumothorax cavity. In June, 1924, she had haemoptysis with the return of tubercle bacilli in the sputum and evidence of slight activity of the left apex. The sputum amounted to 1 to 2 ounces daily. There were signs of activity and excavation in the right upper lobe with generalized signs over the middle and lower lobes. (Fig. 1.)

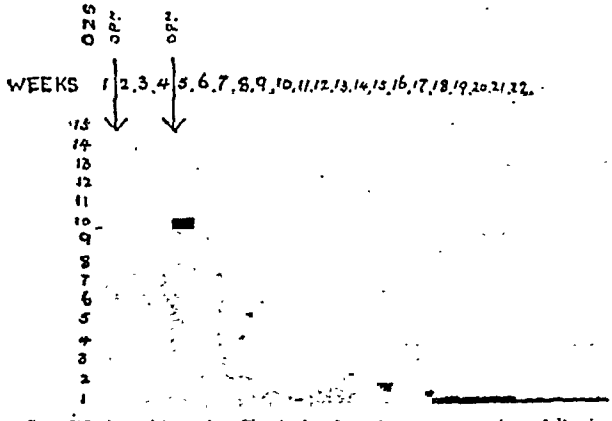
On September 3rd, 1924, under gas and oxygen and local anaesthesia, thoracoplasty (first stage) was performed. Portions of the fifth to the eleventh ribs (inclusive) were removed—total 38½ in. = 96.5 cm. There was only slight reaction to operation. On September 26th, under the same anaesthesia, the second stage of the operation was carried out, portions of the first to the fourth ribs being removed; these offered some difficulty owing to close approximation. Length removed at second stage 11¾ in. = 29.5 cm.; total removed at both stages 50½ in. = 126 cm. There was no noteworthy post-operative reaction.

After-History.—The sputum rapidly disappeared and the temperature became normal. Within three weeks the sputum was free from tubercle bacilli. The patient has kept quite well during the last eighteen months and is apparently cured. Seen recently, there was no cough or sputum; the only complaint was that she was putting on too much weight. (Fig. 2.)

CASE II.—*Bronchiectasis.*

A woman, aged 33, was admitted to Brompton Hospital in December, 1923, for bronchopneumonia, which was followed by pulmonary abscess formation in the right lower lobe. This abscess burst into a localized area in the pleural cavity. The empyema and abscess were drained by me early in 1924, the narrow opening between being dilated. Healing occurred in spite of the presence of the bronchial fistula, and the patient left the hospital well in every way.

In August, 1925, she returned to hospital on account of cough, copious blood-stained sputum of offensive odour, and night sweats; the amount of sputum was 10 ounces daily. Tubercle bacilli were found on one occasion. Lipiodol, administered intratracheally, showed large cavities in the right lung; the left lung showed emphysema. (Fig. 3.)



Thoracoplasty (first stage) was performed on August 29th, portions of the fourth to the eleventh ribs being removed—25 inches in all. The patient's condition after the operation was especially good. The second stage of the operation was carried out on September 16th, when portions were removed from the first to the third ribs—8 inches in all; the total removed at the two stages was 33 inches. Except for a post-operative rise the sputum steadily diminished in quantity, and six weeks later, when she was transferred for convalescence, the sputum amounted to only 1 ounce. There was also a gain in weight at this stage of 3 lb. She has since gained a stone in weight and the sputum is less than 1 ounce daily, being mucoid in type. (Fig. 4.)

CASE III.—*Bronchiectasis.* (See Chart.)

A male, aged 20, was admitted to hospital with bronchiectasis. He had had pneumonia two and a half years previously. He was well until August, 1923, when he suffered from cough and expectoration. From June to October, 1924, he had right artificial pneumothorax treatment; this reduced the sputum from 10 to 12 down to 3 ounces daily. Later there was an increase to 8 ounces daily and pleural effusion developed. From October the sputum increased to 14 or 15 ounces daily.

The first stage of thoracoplasty was performed on January 28th, 1925, under gas and oxygen and local anaesthesia, a total amount of 25 inches being removed from the eleventh to the sixth ribs inclusive. At the second stage, on February 18th, the first to the fifth ribs were partially resected, 14 inches being removed. The total resection amounted to 39 inches. By March 23rd the sputum was reduced to 6 ounces daily; the patient had gained 9½ lb. in hospital.

After-History.—Within four months of leaving hospital the sputum was *nil*. He is now doing a full day's work as chauffeur.

CASE III, bronchiectasis. Chart showing changes in sputum following the two stages of thoracoplasty, and the gradual disappearance of the sputum in the ensuing weeks.

SUMMARY.

1. Thoracoscopy and cauterization of adhesions is a valuable aid to artificial pneumothorax treatment, especially in cases where cavities are prevented from collapsing by adhesions of the band-like or string-like type, not thicker than 1 cm. The number of cases is comparatively small.

2. Pneumolysis can be used as an independent procedure or as supplementary to other operations; it is of no use in bronchiectasis, where basal collapse is required and there is no point of counter-pressure. It is most valuable for uncollapsed apical cavities following thoracoplasty for tuberculosis. Fat appears to be the ideal medium if enough can be obtained. As an independent procedure the results are not satisfactory as the collapse is too localized.

3. Phrenicotomy, or rather radical phrenicotomy, is of value, as an independent procedure, occasionally in the more acute forms of phthisis, where major operations are contraindicated, and in early and, on the worse side, in bilateral bronchiectasis. It is of value as a test of the activity of tuberculous disease in the so-called "better" lung previous to thoracoplasty. As a supplementary procedure it is useful in cases treated by artificial pneumothorax, either where diaphragmatic adhesions are present, or, by reducing the capacity of the hemithorax, it may prevent reopening of cavities when the lung is allowed to expand at the end of pneumothorax treatment. Supplementary to thoracoplasty, it is of much value where the compression of the major operation is found to be insufficient. Haemoptysis from basal cavities can sometimes be controlled by this operation.

4. Thoracoplasty offers considerable hope of amelioration or actual cure in chiefly unilateral tuberculous disease of the lung, where artificial pneumothorax treatment is impossible or unsatisfactory, and where the disease is progressing in spite of careful medical treatment. It is of use also in cases of tuberculous empyema without secondary infection. In the septic tuberculous empyemata the results are not good, but the disease is otherwise almost invariably fatal. Considerable improvement, amounting to cure in some cases, can be obtained by thoracoplasty in unilateral bronchiectasis, but this operation will not collapse the larger bronchi near the hilum, and in some cases a non-odorous mucoid sputum remains after the operation.

5. Pneumotomy should be reserved for localized tuberculous abscesses which are not draining well through the bronchus, and in cases in which the generalized tuberculous process appears to be inactive. In bronchiectasis it should only be used in those cases of large localized abscess formation, and not in the diffuse variety.

6. Bronchostomy is occasionally of great value following drainage of large abscesses; a partial plastic operation on the chest wall should be performed subsequently.

7. Pneumectomy appears to be almost totally contra-indicated in phthisis. In bronchiectasis, although apparently the ideal procedure, it is followed at present by an almost prohibitive mortality (50 per cent.). Further improvements in the technique may eventually make it the operation of choice. The more recent cautery pneumectomy, as practised by Graham in America, has been followed by a much lower mortality than any other lobectomy operation, and offers reasonable hope of eradication of the septic lobe.

My thanks are due ... ... the staff of the Brompton Hospital fc ... in this work, and to Dr. Stanley ... skiagrams, a few only of which are reproduced here.

THE MACROPOLYCYTE.

(With Special Plate.)

BY

W. E. COOKE, M.D., F.R.C.P.ED., M.R.C.P.LOND., D.P.H.

DEFINITION.

THE diameter of a normal polymorph in stained films is from 10 to 12 microns. The term "giant" polymorph or macropolycyte—a name suggested by Sir Humphry Rolleston—may be applied to those polymorphs having a diameter of more than 14 microns. Fig. 1 represents a normal polymorph with five nuclear segments. This has a diameter of 11.5 μ.

ETIOLOGY.

The macropolycyte is found in two widely different conditions—such opposite conditions, in fact, as to make one doubt whether the causation can be the same in the two cases.

The first is in the acute pyogenic infections. Fig. 2 illustrates a macropolycyte from a case of staphylococcal osteomyelitis showing the following blood picture:

Total leucocytes	18,000	per c.mm.
Polymorphs	84	per cent.
Lymphocytes	12	,,
Large mononuclears	3.5	,,
Myelocytes	0.5	,,

Polynuclear count:

I.	II.	III.	IV.	V.
41	43	15	1	0 per cent.

Fig. 3 illustrates a "giant" in a case of streptococcal septicaemia.

Total leucocytes	26,000	per c.mm.
Polymorphs	79	per cent.
Lymphocytes	13	,,
Large mononuclears...	7.5	,,
Myelocytes	0.5	,,

Polynuclear count:

I.	II.	III.	IV.	V.
34	43	21	2	0 per cent.

The staining reactions of the nucleus and cytoplasm are identical with those of other polymorphs in the films. They are rare—encountered perhaps twice or three times a year by anyone constantly examining blood films—and seem always to be associated with a polymorphic leucocytosis and the presence of myelocytes in the peripheral blood. They are, I think, "sports."

The other condition in which macropolycytes occur is pernicious anaemia, and in this disease they are frequently seen. They measure 16 to 21 microns in diameter and are of two distinct types. The first type of macropolycyte is similar in nuclear structure and cytoplasm to the other polymorphs, but the cell is larger, and the nucleus is frequently hypersegmented, as shown in Fig. 4, which illustrates this type. In the second pernicious anaemia type the total bulk of the nucleus is great, absolutely and relatively to the amount of cytoplasm. The nucleus may be of the band form, or have one, two, or as many as fourteen divisions. The basi-chromatin is not so densely massed as in the normal cell, and the cytoplasm contains larger granules, which are neutrophile in reaction. Figs. 5, 6, and 7 illustrate this type. These cells look very like megakaryocytes.

The etiology of the macropolycyte in pernicious anaemia is probably that of the disease itself. The polymorph, even in the absence of the "giant," behaves in a curious manner.[1]

The normal polynuclear count may be taken to lie between the following values:

	I.	II.	III.	IV.	V.	
(1)[2]:	11	25	47	15	2	per cent.
or (2)[3]:	5	35	41	17	2	per cent.

which give readings of 36 and 40 in the left-hand columns and 64 and 60 in the right.

In infections the count moves to the left, as in the cases of osteomyelitis and septicaemia quoted above:

I.	II.	III.	IV.	V.	
41	43	15	1	0	per cent.
34	43	21	2	0	,,

In pernicious anaemia frequently, possibly in all uncomplicated cases at some period of the disease, the polynuclear count shows an increase of the cells of Classes 4 and 5, as in the following examples:

	I.	II.	III.	IV.	V.	
Case 1 ...	8	20	39	22	11	per cent.
Case 2 ...	6	27	40	22	5	,,
Case 3 ...	7	20	44	24	5	,,
Case 4 ...	7	16	29	39	9	,,
Case 5 ...	12	34	26	20	8	,,
Case 6 ...	10	15	38	24	13	,,
Average...	8	22	36	25	9	,,

The left-hand columns give an average of 30 and the right 70. The count is actually right-handed. As far as my experience goes, this does not occur in any other disease.

We have, then, at the outset in pernicious anaemia some factor producing a dysleucopoiesis, and accentuation of this may lead to the production of the macropolycyte.

Some recent papers on the transformation of monocytes in frog's blood, and cells of lymph nodes, into giant cells are suggestive. M. R. Lewis[4] states that giant cells are formed from monocytes in hanging drop preparations of frog's blood. E. Barta,[5] working on tissue cultures of lymph nodes, finds that giant-cell formation takes place at some distance from the surface, and ascribes this to deficiency of oxygen. The addition of embryonic extracts greatly diminishes the effects of oxygen want, and cells in the deeper layers then behave like those with a sufficient oxygen supply. There are many more factors in experimental conditions than simple oxygen want. Alteration in *pH*, gaseous diffusion, surface tension, saline ratios, and lipoid changes must take place and also influence cell metabolism.

Anoxaemia is not the only state responsible for the production of macropolycytes in pernicious anaemia, but whatever the primary general state in this disease is, the marrow seems to take control in the later stages. In addition to the behaviour of the polynuclear count, and the presence of macropolycytes and ichthyoid cells, there is direct proof of this local influence. Walterhöfer and Schramm[6] have scraped and irrigated the medullary cavities of long bones in cases of pernicious anaemia that were apparently moribund. The alteration of the local chemical state effected produced surprisingly good results. That the results may be only temporary does not affect the argument.

These considerations lead to the conclusion that the macropolycytes and pernicious anaemia may be due, either to a primary defect in the chemical composition of the blood, the marrow changes completing the vicious circle, or to a congenital or an acquired condition of the haemocytoblast itself leading to defective haemopoiesis and local biochemical abnormalities, with, later, general effects.

PROGNOSTIC IMPORT.

The first type of macropolycyte, that found in pyogenic infections in association with myelocytes, is, I think, an "accident" and has no prognostic value, except, perhaps, as signs of marrow "stress." Of the second type, the first subdivision, an exaggerated form of the polymorph frequently found in pernicious anaemia, is present at the crises of the disease, and is an index, I think, of local urgency in the haemopoietic tissues, which may or may

not end in temporary recovery. The presence of the second, or megakaryocyte type, is of grave significance, and no case in my experience has lived beyond a few days from its appearance.

THE EXPERIMENTAL BASES OF PROPHYLAXIS IN GONORRHOEA.

BY

KENNETH M. WALKER, M.B., F.R.C.S.,

LECTURER ON VENEREAL DISEASES, ST. BARTHOLOMEW'S HOSPITAL.

THE study of the initial stages of gonococcal urethritis is of extreme importance from the point of view of prophylaxis. Knowledge of the pathology of acute gonococcal urethritis is almost entirely derived from the observations of Finger, who inoculated moribund patients with gonococci and made a detailed examination of their urethrae thirty-six to forty-eight hours afterwards. His description is as follows:

"The gonococci begin to proliferate on the surface of the epithelium which they are about to attack; they are not spread diffusely, but in small groups. At the end of thirty-eight hours they have scarcely as yet penetrated into the epithelium; at the most they have slipped in among the superficial coils at the points presenting the feeblest resistance. If the epithelium is denuded at any point, exposing the connective tissue, the organisms penetrate there more rapidly. They invade the lumina of the crypts of Morgagni with extreme rapidity, and are found in them, lying free on the surface of the epithelium. From this moment, and, indeed, well before this, diapedesis has commenced, the leucocytes are everywhere numerous in the superior layers; a certain number have gained the surface, and one already finds intracellular gonococci."

Finger's observations would lead us to believe that until at any rate thirty-eight hours after inoculation very little penetration of the epithelium by the gonococci has taken place, and that the adoption of appropriate prophylactic measures would stand every chance of success if carried out within this period.

Experimental work has, however, been carried out by other observers using organisms other than gonococcus, which suggests that the diffusion of organisms within the urethra might be more rapid than Finger's observations on the gonococcus would lead us to suppose. Notable among these experiments are those of Palladino Blandini. This observer placed a loopful of *Bacillus prodigiosus* within the meatus of a guinea-pig, and twelve hours later made a necropsy under aseptic conditions and investigated the fate of the organisms since their introduction into the urethra. His choice of *B. prodigiosus* was determined by the fact that on account of its brilliant colouring matter it could easily be recognized. Palladino Blandini found that a widespread diffusion of prodigiosus from the urethra had taken place within twelve hours of inoculation, but that if the animal were allowed to survive for more than twenty hours these diffused organisms were destroyed by the tissues. That the method of diffusion was not through the blood stream was proved by the fact that blood cultures taken from the heart were sterile. In 1909 I repeated and confirmed these findings, and four years later Teale and Embleton proved that what occurred in the urethra was equally true of organisms placed on other mucous surfaces or inoculated into serous cavities. The prodigiosus is capable, therefore, of passing through uninjured mucous membrane, and may be carried from thence along the lymphatic stream and eventually into the thoracic duct. Teale and Embleton's experiments showed, therefore, as mine had already done, that with regard to the generative tract the spread of organisms is into the submucous tissues rather than along the surface. At the necropsy of a guinea-pig killed twelve hours after a loopful of organisms had been placed within the meatus no infection of the surface of the posterior urethra, bladder, ureter, or pelvis was found, although extensive dissemination by the lymphatics had taken place. The organism employed for this experiment was, however, *B. prodigiosus*, and it is possible that what is true of that organism is not true of the gonococcus. *B. prodigiosus* is a non-pathogenic organism, whereas the gonococcus, at any rate in the human being, provokes immediate and intense reaction of the tissues. Nevertheless, on repeating this experiment with a mixture of *Staphylococcus aureus* and diphtheroids I obtained similar results, and these organisms, unlike *B. prodigiosus*, are pathogenic to guinea-pigs.

In the light of these experiments Finger's contention that there occurs little or no penetration of the human urethral mucous membrane by the gonococcus for thirty-eight hours seemed open to doubt, and for many years I awaited an opportunity of throwing new light on the situation. Would organisms placed within the meatus of a human being behave in the same way as organisms inoculated into the urethra of a guinea-pig? Two years ago a chance of carrying out a somewhat similar observation on a human being presented itself.

A patient was admitted under my care into the Royal Northern Hospital suffering from an impassable stricture in the bulbar urethra and an early carcinoma of the glans penis. At 11 a.m. I placed two loopfuls of *B. prodigiosus* within his meatus. At 6 p.m. I opened the urethra on the bladder side of the stricture without having previously attempted to pass any instrument. After dividing the stricture through the wound in the perineum, a sterile cotton-wool swab on a holder was passed along the urethra from the opening in the perineum to a point 2 inches from the meatus and an agar plate inoculated. A second swab was similarly passed until it reached a spot 1 inch from the meatus, and another plate inoculated. My object in doing this was to ascertain whether in the seven hours' interval the organism had spread along the surface of the urethra towards the bladder. The fact that both plates remained sterile showed that no surface spread had occurred. I then carried out a partial amputation of the penis. Later multiple transverse sections were made through the amputated penis. These sections were stained with methylene blue and carefully examined under an oil immersion objective for organisms within the tissues. On the surface of the urethra no organisms could be found, but in the submucous tissues large clumps of small bacilli morphologically resembling *B. prodigiosus* were visible. These collections of bacilli were either in the form of more or less circular colonies or else were spread out along a line, and although no proof could be furnished of this, their distribution suggested that they were lying within the submucous lymphatics.

This observation, therefore, so far as it went, led me to believe that what was true of the behaviour of *B. prodigiosus* within the urethra of a guinea-pig was equally true of its behaviour when placed within the meatus of a human being.

By the courtesy of Dr. Mervyn Gordon I was able to repeat my observations in a monkey. Similar results were obtained.

A loopful of Hoffmann's bacillus and *Staphylococcus aureus* was placed within the meatus, care being taken to inflict no damage whilst the inoculation was being made. Eight hours later the monkey was killed by means of chloroform. Transverse sections were then prepared through the urethra at different levels and organisms searched for. In this case a few Gram-positive bacilli and cocci were found lying in the lumen of the urethra and also deep to the epithelial cells, but further up, an inch from the meatus, larger clumps were found in the submucous layers.

The above experiments suggest, although they do not prove, that in any infection of the urethra there is an immediate dissemination of organisms through the lymphatics as well as a slower spread which is associated with the signs of inflammatory reaction. In the majority of cases the tissues are able to deal with the immediate lymphatic invasion provided that it is not too liberally reinforced by fresh supplies from the surface. The chief point of practical interest is the bearing of these observations on prophylaxis in gonorrhoea.

Clinical observations, and particularly those carried out at the prophylactic stations established by the American Army in Paris during the war, showed that the chances of success of any prophylactics are directly proportional to the time that has elapsed since exposure. Since the gonococcus is easily destroyed by weak disinfectants while lying on the surface of the urethra, irrigation with weak permanganate solution is found to be effective in the great majority of cases, provided the patient presents himself for disinfection within a few hours of exposure. The longer the interval between exposure and disinfection, the more often does the disinfection process fail. No absolute time limit, however, can be laid down to guide us in arriving at a decision as to

when a prophylactic measure is likely to be of use, and the evidence given before the Trevethin Committee on this point by different authorities was conflicting in the extreme. Individuals vary in their susceptibility to gonococcal infection, and for this reason it is advisable to wash out the urethra even although twenty-four or forty-eight hours have elapsed since exposure.

From the fact that irrigation is successful in safeguarding the patient in the great majority of cases, provided it is carried out within three to four hours of exposure, it may be surmised that the tissues are generally capable of dealing with the more rapid dissemination of organisms occurring through the lymphatics, for if this were not so prophylactic measures would be of little avail. But it is within the experience of most urologists that from time to time prophylactic measures fail, even although carried out within an hour of exposure. I can remember several instances in which the urethra was washed out immediately after exposure, either by a competent orderly or else by the patient himself, and yet gonorrhoea developed. It is possible that these failures of prophylaxis are to be explained by an inability of the patient's tissues to deal with the rapid lymphatic dissemination. The problem is complicated, however, for we know that not only do individuals vary in their resistance to the gonococcus, but also that different strains of the organism exist with different grades of virulence. The reaction of the tissues to these different strains varies, as is shown, not only by the acuteness of the attack that develops, but also by the length of the latent period.

It has been proved by experiment and by clinical practice alike that the ideal fluid for prophylactic irrigation is of a non-irritating nature with the maximum power of penetration. Could a bactericidal fluid be obtained which was capable of being absorbed to some extent by the lymphatics, it is possible that a still higher ratio of success might be achieved, and that the small percentage of cases in which prophylactic measures miscarry might be abolished. But before these ideals can be reached more research is necessary, and it is possible that the knowledge which will be of the greatest use will be that which throws light on the part played by the lymphatics in disease and in health.

NYSTAGMUS IN AN INFANT.

BY
G. MACLEOD MILLAR, M.B., CH.B.,
AND
JAMES ALEXANDER WILSON, O.B.E., M.D.,
CAMBUSLANG, GLASGOW.

THE following case has been under our observation for about two years and seems worth recording.

The patient is a child with paralysis of the third nerve and nystagmus. The mother has five children living, but she has also had two that were stillborn, and one that died shortly after birth. Several of her confinements have been "instrumental," the history of these suggesting some maternal malformation. When the patient was born instruments were again required, and soon after birth it was observed that "the right eye was too much closed." There was also a suggestion that the right side of the face was paralysed, but, if so, it soon passed away. It was further observed that the right eyeball diverged. At the end of two months the drooping of the right upper eyelid disappeared.

When first seen the child was 9 months old; there was no evidence of ptosis, but the reverse, for the lid was now unnaturally drawn up, exposing part of the sclerotic above the cornea. The right eye could only be closed imperfectly, and the child seldom closed it; even when in sleep the eye remained open. The right eyeball was still divergent; it could be moved up to, but not beyond, the middle line, and it could not be raised or lowered. The right pupil was dilated, and did not seem to react to light. Moreover, this eye had rotatory nystagmus. The left eye seemed normal, except that it also exhibited rotatory nystagmus.

A year later both upper eyelids seemed normal. The mother stated that the child now closed both eyes, but that the right tended to open during sleep. The right eye was still divergent, but came in when the left was covered—not, however, beyond the middle line. The pupils were now equal. There was still rotatory nystagmus in both eyes, but the range was less. The child tended to turn the head to the left, as if endeavouring to use both eyes. The fundus in both eyes was normal.

A few months later the condition was much the same. When the child looked down, the right upper eyelid did not come so far down as the left.

Here, then, we have a lesion that in effect produces abeyance of function of the greater part of the higher area of the brain that controls the oculomotor apparatus of the right eye, and with this is associated nystagmus affecting both eyes. It is interesting to note that the paralysis of the levator palpebrae was replaced by spasm, thus resembling the cyclic affections of the third nerve.

Nystagmus occurring in a miner is not an entity by itself, and should not be considered in a detached manner. The neurasthenia that attends the later stages in the miner is in great measure fostered by the legal recognition of injury received and the elaborate provisions made for dealing with compensation.

Imperfect retinal images are common to all cases of nystagmus, or there is interruption of the transmission of these as afferent impulses. The miner straining to see while at work at the black and dark coal face has very imperfect images to guide his labours, while often the actual onset of the disorder is occasioned by a blow.

In the case here recorded there is interruption of the associated efferent impulses, with loss of some higher control. Nystagmus is sometimes associated with mental defect, and it is sometimes a terminal manifestation in exhausting diseases. In the background of all these there is probably loss or enfeeblement of the higher control, with consequent release phenomena.

SYMMETRICAL HYPERKERATOSIS OF THE EXTREMITIES.

(? *KERATODERMIA BLENNORRHAGICA.*)

BY
J. BEATTY, M.D., M.R.C.P.,
MEDICAL OFFICER IN CHARGE OF THE DEPARTMENT OF SKIN DISEASES, ROYAL INFIRMARY, CARDIFF.

THE following case of symmetrical hyperkeratosis of the extremities is of interest because of its association with the gonococcus.

A married woman, aged 51, presented herself at the dermatological clinic of the Royal Infirmary, Cardiff, on October 16th, 1925. She stated that the condition started as a horny mass under the left great toe about a month previously and soon spread over the sole of the foot, simultaneously appearing on the sole of the right foot. There were soreness and burning sensations, and the mass of horny tissue caused pain on walking. Immediately previous to the attack her left ankle swelled and became painful; later, shortly before she came to the clinic, there were pain and swelling in the left knee.

On examination the soles of both feet, including the sides and backs, showed heaped masses of horny skin, broken here and there by cracks. At the points of the toes cornified matter projected for a quarter to half an inch, almost like horns. There was no exudation, and at one or two points where a portion of the mass had been detached the skin was pink, soft, and dry. In front of each knee there was a similar but less marked horny thickening in a well defined patch. There were also a few small patches of thickened epidermis on the left palm, but no rash of any kind elsewhere on the body. Her left knee was somewhat swollen, tender, and slightly reddened. Her left ankle was slightly swollen, but she made no complaint of pain. There was some general malaise.

I asked Dr. Erie Evans, in charge of the venereal disease clinic for women, to examine, and if necessary, treat her. Dr. Evans reported that on making a bimanual and other examination nothing abnormal was found, but that she had taken smears from the vagina, cervix, and urethra. On these Dr. Scholberg, pathologist to the Royal Infirmary, reported that gonococci were present in the films from the urethra and cervix, but not in that from the vagina. Dr. Evans then treated the case, giving trimine intramuscularly and rhubarb and soda mixture by the mouth.

By October 23rd the left knee was much improved, and the malaise relieved; there was still slight swelling of the left ankle. The urethra and cervix were treated with protargol, and contramine

pessaries were applied every night; hexamine mixture was administered.

On October 30th the joints were normal.

From November 6th to January 8th, 1926, local treatment only was employed.

On January 22nd, February 19th, and March 12th 0.25 c.cm. of contramine was given intramuscularly. On February 26th all local treatment was discontinued.

Films from the urethra, vagina, and cervix, taken on March 5th and 12th, were reported to be free from gonococci.

During this period the hyperkeratosis was not treated except by frequent soaking in hot water, and the condition slowly improved. Some increase, however, occurred on the palms, the right palm, which when first seen had shown only doubtful indications, being affected as well as the left. Both palms were nearly covered with thickened epidermis, and the normal lines were deepened. By the time that her treatment at the V.D. clinic ceased the patient had sufficiently recovered to be free from discomfort, and she stopped attending the hospital.

As it seemed desirable to obtain confirmatory evidence of the gonococcal origin of the condition a complement fixation test was made. This, however, could not be carried out till July owing to difficulty in obtaining a suitable antigen. Dr. Scholberg reported that the result was negative in all dilutions. The Wassermann test had been carried out in October, 1925, with a negative result in all strengths except 40 per cent., where it was weakly positive.

On September 3rd, 1926, the patient attended at the dermatological clinic at my request, when I found that the masses of horny epidermis had largely disappeared, but that there was still a border of the condition at the sides and backs of the feet, especially at the heels, also on the balls of the toes, especially the great toes. A little keratosis was noted at the points of the toes. On the knees there was a thin patchy scattered keratosis, and the palms showed patches here and there, rather more on the left palm. There was some scaliness and discoloration of the skin at the outer side of the left ankle.

It is difficult to be sure that this was a case of keratodermia blennorrhagica, first described by Vidal in 1893, and by others since. In favour of this diagnosis are the rapid increase of the eruption when it first appeared, its symmetry, its association with inflammation of two joints, and the fact that gonococci were definitely found in the smears from the urethra and cervix. On the other hand, there were no obvious signs (discharge or inflammation) in the genital region, the complement fixation test was negative, and there was no evidence in the skin lesions of any vesicle formation, such as Sabotka[1] and others have described as marking some of these cases. It may, however, be urged in reply to the last objections that the fixation test was not applied till long after the films from the genital region had been found negative, and that the absence of vesicle formation was due to the chronicity of the accompanying condition, which even in the joints was only subacute. Other possible causes seem excluded, so I think one is justified in believing that the case was one of keratodermia blennorrhagica.

Memoranda:

MEDICAL, SURGICAL, OBSTETRICAL.

TWO-STAGE OPERATION FOR CLEFT PALATE.

ALL surgeons have experienced difficulty in obtaining uniformly good results in operations for cleft palate when the cleft is complete, involving both hard and soft palate; when the cleft is exceptionally wide and its closure involves considerable shifting of the lateral flaps; and when the condition exists in adult or adolescent patients as the result of neglect or failure of earlier operation.

Success depends upon adequate circulation in the flaps and their approximation without tension. Failure is due to the difficulty experienced, in the types of cases referred to above, in securing both conditions. The disturbance of circulation involved by the free lateral incisions and extensive detachment of the lateral flaps necessary to ensure their approximation without tension is considerable, with the result that their nutrition is lowered and their power to heal greatly diminished. It is a common and disappointing experience to find that after an apparently successful operation union of the flaps has failed wholly or in part. None of the devices used for eliminating undue tension, though of themselves adequate, have given certain results, and the reason for the failure appears to be impaired vitality of the flaps due to inadequate circulation.

For some time, in cases where the necessary disturbance of tissue is such that the circulation of the flaps is likely to be seriously reduced, it has been my custom to perform the operation in two stages. At the first sitting the lateral incisions and separation of the flaps are carried out and they are freed until they approximate without tension. No attempt is then made to pare the edges nor to suture them together. Two silkworm-gut sutures, passed through the flaps some little distance from their inner margins, are tied just sufficiently tightly to keep the edges close together, the lateral incisions are packed with gauze, and the patient is sent back to bed.

The second stage of the operation is performed about ten days later. By that time the circulation of the flaps has been re-established and their vitality is adequate for healing to take place rapidly and smoothly. Very little disturbance of the flaps is called for at the second operation. The edges are pared in the usual way; they are gently pushed together and sutured with fine silkworm-gut. Two silkworm-gut tension stitches are again inserted to take tension off the suture line, and the lateral grooves are packed with gauze.

By this method a very great improvement in results has been obtained, and many cases which were regarded as inoperable, or in which previous operations had failed, have been successfully treated. Among these were a number of patients whose ages ranged from 12 to 28 years.

I am indebted to Mr. Harold Round, honorary dental surgeon to the Queen's Hospital, for suggestions and help in devising a method which would secure both the conditions essential for success.

Birmingham. WILLIAM BILLINGTON, M.S., F.R.C.S.

PULMONARY EMBOLISM FOLLOWING CHILDBIRTH.

A CASE very similar to those recorded by Drs. W. J. Young and T. McCulloch (November 6th, p. 835) came under my notice in April last. I received an urgent call, and on arrival about five minutes afterwards found the patient dead. She had been confined about two weeks previously, and the midwife who had been in attendance stated that everything had been normal. The patient had been getting up for three or four days previously; the day before she had been out of doors for about an hour, and had felt quite well, except for a slight pain in the left groin. On the morning of her death she arose feeling quite well, and while preparing her husband's breakfast she suddenly fell down and died in a few minutes.

This was obviously a case of pulmonary embolism following femoral thrombosis. These cases impress upon us the careful watch which should be kept for the somewhat insidious onset of thrombosis during the puerperium and the prolonged rest that is necessary once the condition is established.

Warrington. J. J. MANNING, M.B., B.Ch., N.U.I.

A PATIENT of mine recently died with dramatic suddenness from pulmonary embolism following childbirth. She was a married woman, aged 36, and the confinement was her sixth.

Delivery was normal; my last visit to her was on the fourth day of the puerperium, when to all appearances she was well. I had not left the house more than ten minutes before she died. Her husband explained to me how, during a conversation with him just after my departure, she sat up in bed and suddenly complained of very severe pain in the left chest. She gasped for breath, clinging to the bedside, her face, first ashen grey, rapidly became cyanosed, and in a few minutes she expired.

I was unable to ascertain any other possible cause of death, for I had examined her chest and heart at my first visit.

Tarland, Aberdeenshire. C. G. SALVESEN, M.B., Ch.B.Ed.

OVERDOSAGE OF HYOSCINE.

As injections of hyoscine hydrobromide are being widely used for the treatment of chronic cases of encephalitis lethargica with the Parkinsonian syndrome in order to reduce the rigidity, the following account of overdosage may be of use.

M. W., aged 52, was admitted to the Hull Royal Infirmary with marked rigidity of the legs, and to a lesser extent of the arms, which had come on after a definite attack of encephalitis lethargica.

He was given hyoscine hydrobromide 1/100 grain once a day. This was later increased to 1/100 grain twice a day, and eventually to 1/75 grain twice a day. The rigidity was so much diminished that he was able to walk with, and occasionally without, assistance, and to feed himself, which he was unable to do on admission.

The treatment was occasionally omitted for a few days. During its course, and shortly before he was discharged, he showed the following symptoms, which lasted some hours. Twenty minutes after an injection of 1/100 grain, twitchings of arms and legs, profuse sweating of body and limbs, pallor of nose, stuporose condition, eyes closed, no loss of rigidity, picking movements of fingers, pupils dilated, no response to questions, no remembrance of having any indisposition at all. He stated that he felt quite well when he came round, and took food well.

STANLEY E. DENYER, C.M.G., M.D.,
Physician, Hull Royal Infirmary.

Reports of Societies.

DIABETES AND PREGNANCY.

AT a meeting of the Edinburgh Obstetrical Society on December 8th, 1926, Professor R. W. JOHNSTONE, the President, in the chair, Dr. C. G. LAMBIE read a paper on diabetes and pregnancy.

Dr. Lambie said that diabetes and pregnancy were rarely associated, because diabetes caused atrophic and sclerotic changes in the ovaries and uterus, with resulting sterility, disorders of menstruation, and sexual frigidity. These functional disturbances could often be rectified by the use of insulin, except when organic changes were advanced, as in the more chronic cases. Pregnancy exacerbated a pre-existing diabetes and might be the starting-point of the malady in individuals predisposed by heredity or otherwise. The factors leading to the deterioration in sugar tolerance were: (1) absorption of products of protein hydrolysis from the placenta during the first three to four months—a condition analagous to infection; (2) the emotional excitability of the earlier months causing glycogenolysis in the liver; (3) overeating, after the period of morning sickness was over; (4) the necessity for giving a good deal of carbohydrate to prevent acetonuria; (5) hyperactivity of the thyroid and pituitary glands during the later months. Improvement in tolerance was commonly observed towards the end of pregnancy, while, simultaneously, there was an increasing tendency to acetonuria. Both these phenomena were attributable to the large amount of carbohydrate utilized by the foetus. The islet tissue of the foetus underwent marked hyperplasia and hypertrophy to meet the increased functional demands. There was no good experimental evidence that insulin passed from the foetus to the mother. During labour the blood sugar rose slightly, but after delivery there was a sharp rise, the hyperglycaemia lasting for twenty-four to forty-eight hours. Thereafter an improvement in tolerance occurred, and might be accompanied, in insulin-treated cases, by hypoglycaemia. This was due either to a return of pancreatic function, or to excretion of carbohydrate as lactose in the milk, or to replenishment of the glycogen reserves after their depletion during labour. In the latter case it might be quite shortlived and be followed by another fall in tolerance, after which there might be a gradual improvement. Acetonuria during labour was due to (1) depletion of the glycogen reserves in order to provide carbohydrate for the supply of energy for muscular contraction, (2) anaesthetics, (3) starvation, (4) haemorrhage, and (5) sepsis. In diabetes, coma might result. After delivery the tendency to acetonuria disappeared, more fat could be taken, and the necessary calories might be given with a smaller intake of glucose.

When diabetes coexisted with pregnancy both the maternal and foetal mortality were high. Hyperglycaemia in the foetus, which was secondary to maternal hyperglycaemia, resulted in hydramnios, the development of an excessively large foetus, and hyperplasia of the islets of Langerhans in the foetal pancreas. Hydramnios might be caused by foetal diuresis together with endosmosis, due to high osmotic pressure of the saccharine foetal urine. Hypoglycaemia, due to excessive insulin secretion by the hyperplastic islet tissue, was a possible cause of death after birth. These conditions, with their associated obstetrical complications, were avoided by the use of insulin. Insulin also raised resistance to infection and diminished the susceptibility to puerperal sepsis. Diabetes had to be distinguished from other forms of glycosuria occurring in pregnancy—namely: (1) early alimentary glycosuria, (2) renal glycosuria, (3) lactosuria, (4) glycosuria due to carbohydrate starvation, and (5) late alimentary glycosuria. The latter might closely resemble diabetes, and be liable to similar complications; its most outstanding feature was its rapid disappearance within about ten days after delivery. It was probably of hypophyseal origin. In some cases hyperthyroidism might be a cause of glycosuria. Insulin had improved the prognosis, especially as regards the life of the mother. Some cases now passed through pregnancy without loss of tolerance; pregnancy might go on to full term and a healthy child might be born. In treatment the diet must contain a relatively high proportion of carbohydrate in order to avoid acetonuria. After delivery, a high fat low carbohydrate diet might be given, and it then became possible to reduce or abolish the dose of insulin. The calorie requirements were about 35 calories per kilo per diem, and the protein minimum was approximately 1.2 grams per kilo per diem. Insulin was administered in the usual way; it did not harm the foetus, even when minor attacks of hypoglycaemia occurred. Induction of abortion was indicated (1) where diabetes had existed prior to pregnancy and the patient was unwilling to submit to continuous supervision under suitable conditions; (2) in very emaciated, ill-nourished subjects; (3) where there was rapid loss of tolerance in spite of treatment; (4) in cases of acidosis with uncontrollable vomiting. Where a large foetus was expected premature labour might be induced, or Caesarean section under nitrous oxide and oxygen anaesthesia might be performed. Labour was best conducted under hyoscine and morphine narcosis. During labour the usual doses of insulin, together with a very liberal allowance of easily assimilable carbohydrate, should be given to prevent acidosis. Dihydroxyacetone was of especial value here.

Rupture of Caesarean Scar.

Professor J. A. KYNOCH described two cases of rupture through a previous Caesarean section scar during pregnancy, the two cases having been encountered within a period of two months. In the first case the patient had had two Caesarean sections performed, and she was again nearly at full term. The clinical features in this case were severe collapse preceded by several hours of abdominal pain and sickness, during which time the patient had walked several miles in search of work. Operation was performed immediately on admission, and an aperture about the size of a five-shilling piece was found at the lower end of the scar, which was thin and translucent for its whole length, the peritoneal coat alone being intact. There was a considerable quantity of free blood in the peritoneal cavity. Supravaginal hysterectomy was performed, and the patient left hospital three weeks after admission. The second patient was also eight months pregnant, and had had one previous Caesarean section performed. She was suddenly doubled up with pain, and had a fast pulse and hurried respirations, the rupture being complicated by an acute lobar pneumonia. Rupture was diagnosed, and the abdomen opened under local anaesthesia. The rupture was found to be five inches in length, and the membranes bulged through. After removal of a dead child the wound was sutured and the patient sterilized. After a somewhat

stormy convalescence, owing to the chest condition, the patient eventually did well, and was discharged four weeks after operation. Professor Kynoch then went carefully into the statistics of rupture after a previous Caesarean section, and contrasted the results of the classical and lower uterine segment incisions. He stated that the most frequent causes of rupture seemed to be infection with defective coaptation of the wound edges, catgut as a suture material, and the attachment of the placenta to the line of the incision. In both of his cases there had been a febrile convalescence at the previous Caesarean sections, and catgut had been the suture material employed. He favoured silk as the best suture material for Caesarean section, and thought catgut most unsuitable.

GASTRIC AND DUODENAL ULCERS.

AT a meeting of the Cardiff Medical Society on November 23rd, 1926, with Dr. A. HOWELL in the chair, Mr. J. BERRY HAYCRAFT read a paper on the diagnosis and treatment of gastric and duodenal ulcers.

Mr. Haycraft described the routine method of examination of cases in the surgical unit, which consisted of clinical history, physical examination, *x*-ray examination, fractional test meal, examination of stools for occult blood, red cell count, blood compatibility in case of transfusion being necessary, and the Wassermann test. He emphasized the importance of obtaining an accurate clinical history of the symptoms of the disease from its very commencement, and described in detail the symptoms and methods of questioning the patients. This was regarded as the most important factor in making a diagnosis. The *x*-ray examination should be conducted by the radiologist and the surgeon together; screen examinations give a better indication of the nature of the lesion than films. The fractional test meal had been of value in confirming the diagnosis in only half the cases, but the detection of the presence of occult blood in the faeces had often been the conclusive factor. In considering what type of operation was of most value, Mr. Haycraft emphasized particularly the need for early diagnosis, since this rendered the operation as a rule simpler and less dangerous. As a rule duodenal ulcers and simple ulcers close to the pylorus could be cured by the operation of gastro-jejunostomy, but ulcers on the lesser curve and those adherent to the liver or pancreas required some form of excision or partial gastrectomy. In these old-standing adherent cases partial gastrectomy was often very difficult, and the mortality was higher than that of gastro-jejunostomy, but by earlier diagnosis and treatment some of these more severe operations could be avoided. Sleeve resection was not a good operation unless combined with gastro-jejunostomy. Two cases of hour-glass stomach where gastrectomy was not feasible had done well with gastro-gastrostomy combined with gastro-jejunostomy. Careful pre-operative treatment was most important, particularly the rectal administration of glucose, and, if necessary, one or more transfusions of blood. Similar post-operative measures to combat shock were indicated.

PROGNOSIS.

AT a meeting of the West Kent Medico-Chirurgical Society at the Miller General Hospital, Greenwich, on December 10th, 1926, Dr. H. NOCKOLDS, the President, in the chair, Dr. ROBERT HUTCHISON delivered the Purvis Oration on the subject of prognosis. In the course of his address Dr. Hutchison showed how prognosis was affected by changes of type in disease and the introduction of new methods of treatment. Scarlet fever was less severe, while measles and pneumonia were more severe than in the previous generation. Prognosis was considered under three headings—namely, the expectation of life in the healthy; in acute self-limited disease, such as typhoid fever and pneumonia; and in chronic diseases, whether curable or *not*. In the first case heredity was the most important factor in promoting long life, but occupation and personal habits had also to be considered. The organs chiefly concerned in longevity were the heart, kidneys, and lungs. Though it was difficult to estimate the resistance of bacterial infection, no patient less than 40 years of age should die of acute disease, and the London Hospital records showed a 10 per cent. increase of mortality for each decade. Bad signs were: an increased pulse rate, low blood pressure, disturbance of the first sound at the apex, and refusal of food. The temperature was unimportant, except in little children and old people. Sinking down in bed was an unfavourable indication, and the tone of the voice should be noted. In acute disease prognosis might be upset by a sudden heart failure. The chief sources of error were: faulty diagnosis, paying too much attention to physical signs and too little to the patient, failure to allow for complications, inability to estimate the reserve power of the heart, and refusal to face facts. Such words as "never" and "almost" should not be used in prognosis, and no unnecessary prophecies should be given.

JAMES MACKENZIE INSTITUTE.

AT the James Mackenzie Institute for Clinical Research, St. Andrews, on November 30th, 1926, Mr. A. ERNEST MAYLARD read a paper on the bearing of such conditions as high blood pressure, glycosuria, and albuminuria on the performance of surgical operations.

In the case of high blood pressure it was not, he said, so much the symptom itself that demanded consideration as the condition on which it depended, for where the rise in pressure was due to kidney, heart, or artery disease grave lesions connected with these viscera introduced factors of greater moment than the symptom they produced. Save in exceptional cases where the systolic pressure exceeded 240 and the diastolic 140 the risks connected with operation appeared to be negligible. Charles Moots of *Toledo*, U.S.A., had suggested as a working hypothesis that primary consideration should be given to the "pressure ratio"; this ratio was found by dividing the pulse pressure by the diastolic; it was considered "ideal" when it stood at 50 per cent., but when below 25 per cent. or above 75 per cent. it was "very grave."

Operations upon patients suffering from glycosuria, as represented by diabetes, did not appear to add any very serious risk or impediment in their performance, as best illustrated by the success that had attended amputations for diabetic gangrene. Inasmuch, however, as the disease could be controlled to a very large extent, and the patient benefited by the preoperative administration of insulin, operations of expediency could be undertaken without any fear of untoward results; experience further proved that wounds healed as well as when no such disease existed.

In discussing the subject of albuminuria as it affected operation, Mr. Maylard said that consideration must be directed more to the cause of the symptom than to the mere presence of albumin in the urine. By simply reasoning on the matter it might be supposed that, when the albuminuria was dependent on a pathological condition of the kidney, the gravity of an operation would be considerably increased; but practical operative experience indicated that unless the disease of both viscera was very advanced but little risk was added to the performance of an operation. Albumin in the urine dependent on most other conditions, particularly if only a trace, could be looked upon as practically of no moment, even when an operation was not imperative but merely expedient.

In conclusion, Mr. Maylard said that he had had the valuable collaboration of Professors Wilkie and John Fraser of Edinburgh, and of Professors Archibald Young and Peter Paterson of Glasgow, in investigating the results of operations on patients suffering from one or other of the three symptoms under discussion. Their investigations and opinions were practically similar to those undertaken and given by other surgeons. It all practically amounted to this, that with the usages of modern surgery, in the most comprehensive acceptance of the term, combining expeditiousness and careful technique, aided by adequate medical and dietetic treatment, and the right selection of an anaesthetic best suited for the particular case, there were but few sufferers from any one of the three symptoms of high blood pressure, glycosuria, and albuminuria in whom operations of expediency or necessity involved any additional risk.

Reviews.

A BEGINNER'S GUIDE TO MEDICAL TREATMENT.

IT is not surprising that Dr. ROBERT HUTCHISON'S former pupils have often asked him to publish the lectures on elementary therapeutics which he used to give at the London Hospital, and it is gratifying that he has at last been induced to do so. His book *The Elements of Medical Treatment*[1] is a model of brevity, clearness, and sound judgement.

While emphasizing the value of radical treatment where possible, and the ease with which symptomatic treatment may be abused, Dr. Hutchison recognizes that in many cases the latter alone is available. Hence many of his chapters deal with such general symptoms as fever, pain, insomnia, dyspepsia, and heart failure. Under each heading a short account is given of the indications for treatment, followed by a description of the general management of the patient, the diet suitable for the case, and the drugs which relieve the symptom. The treatment is illustrated by prescriptions, to each of which is appended a brief account of the reason for the use and combination of the drugs. The book is brought well up to date by the inclusion of chapters on the use of insulin in diabetes, on endocrine treatment, on bacteriotherapeutics, and on psychotherapy. The wise conservatism of Dr. Hutchison is shown by his statement that, with the exception perhaps of the endocrines, no remedies have been used with less discrimination than vaccines, nor with less of the healthy scepticism which should characterize the therapist. And of endocrines he says that, apart from insulin, only three are of proved therapeutic value—namely, those from the thyroid, the suprarenal, and the pituitary.

The book is written in an easy, conversational style, and should achieve Dr. Hutchison's aim in being useful to the medical student preparing for examinations, and as an introduction to more complete and detailed treatises.

INSULIN IN THE CONTROL OF DIABETES.

THAT a second edition of LAWRENCE'S *Diabetic Life*[2] should appear in less than a year after the publication of the first seems sufficient proof of its usefulness in "its main object [to quote the author's preface] of simplifying the modern treatment of diabetes for both patient and practitioner." Comparatively few changes have been made; the line-ration scheme, which the author introduced in his first edition (reviewed by us on February 27th, 1926), has been rearranged and somewhat simplified. Fuller examples of diet have been added, as well as an excellent table of treatment for emergency use in coma. The author has included an important observation on page 13 regarding the widespread idea that if a patient who has once begun the use of insulin should discontinue its administration the diabetes will become worse. "This," he says, "is quite wrong. The omission of insulin leaves the patient in the same condition as before, or sometimes a little better." This observation is well worth emphasizing, as is a further remark on page 66: "My experience has been that most cases who have been careful about their diet and insulin have been able to reduce their insulin dosage considerably during the first six to nine months of treatment." Perhaps if the author had favoured "high diets and high insulin" rather than "moderate diets and moderate insulin" he would have found his patients even better able to reduce or to omit entirely their insulin. In a footnote on page 53 another noteworthy dictum occurs: "No careful practitioner should be deterred from giving a severe case insulin, either because no blood sugars are available, or because admission to a hospital is impossible." This is sound and bold advice which can safely be followed. We are glad to find that there is no drawing back from the opinion expressed in the first edition, that "starvation has now become unnecessary" in the treatment of diabetes. The book is an admirable little guide to the control of diabetes by diet and insulin. The publishers have improved the legibility of the printing by the use of a paper with a different face.

Dr. CONYBEARE has compiled a short manual for the use of diabetic patients, entitled *Self-Care for the Diabetic*,[3] which contains just so much scientific explanation of the principles underlying treatment as will help a patient of average intelligence without confusing or alarming him. One drawback which any diabetic patient must experience is the fact that in order to live he must never forget his disease. The criticism is sometimes heard that it is a pity to put into a patient's hands a book about his disease. But in diabetes the patient is compelled to think about his condition and study his symptoms. Dr. Conybeare deserves congratulation on his book, which will inform a patient without giving cause for unfounded fears. The principles of dieting are made interesting and easy to grasp, though we find it difficult to agree with his warning (on page 19) that all breads, whether white or brown, are unsuitable for any except the milder cases of diabetes. As a matter of experience even the severest cases may, with the help of insulin, take considerable quantities of white or brown bread with advantage to their nutrition as well as their palates. But it is noticeable that in many of his specimen diets Dr. Conybeare shows some reluctance to be generous in his carbohydrate allowance—a very common and apparently very English attitude. For instance, on page 29 a patient's chart is shown giving the information that on a diet of 1,960 calories a patient weighing 164 lb. (dressed) motored 100 miles, and was very tired. The ratio of fat to carbohydrate and protein is given as 160 to 55 and 75. Both the carbohydrate content and the calorie value of the diet are on the meagre side. Elsewhere the author complains that diabetic diets are expensive, chiefly because of the fat they have to include. But it begins to be time that "high fat" diets for diabetics gave place to ordinary diets with adequate insulin. The chapter on "hygiene for the diabetic" is one which every diabetic patient should learn by heart. Appendix I consists of a brief list of common foodstuffs and their values; it is as good as any we have seen, and commendably shorter than most. The volume is printed in the excellent type of the Oxford Medical Publications.

TREATMENT OF CHRONIC ARTHRITIS AND RHEUMATISM.

IN his *Treatment of Chronic Arthritis and Rheumatism*[4] Dr. H. WARREN CROWE advocates a method of vaccine treatment which he finds to be of value to patients in an early stage. His views on the bacteriology of these common disabling affections are here clearly enunciated, but as they are in some respects different from those usually held he is wisely giving his detailed description of this subject in a supplementary volume. He concludes that osteo-arthritis, which is a local disease, as well as most forms of non-articular rheumatism, are due to streptococci, whereas rheumatoid arthritis, which is a general disease, is due to a certain group of staphylococci described by him in 1912, one of which he called *Micrococcus deformans*. In most instances, however, both infections are at work, and accordingly in this group of mixed arthritis both vaccines should be employed. While holding that the microbic conception of these diseases is fundamental, and pleading for a trial of these vaccines, he is emphatic on the importance of removing any septic focus, and points out that if such a focus is left cure may be rendered impossible, or that if apparent cure does take place it will be temporary only. Infection of the small intestine is regarded as more significant than that of the

colon. The section on clinical diagnosis and prognosis contains evidence of much careful observation, and mentions many clinical points to look out for.

The details of treatment are carefully laid down, and particular stress is placed on the importance of giving small doses of vaccine, as sensitization is prone to occur; Dr. Crowe disapproves of the large doses of streptococcus vaccines sent out by clinical laboratories, and thinks that tragedies have not more often resulted because the streptococci used are harmless. Daily estimations of the body weight are regarded as important in calculating the dose of vaccines. Methods of treatment other than by vaccines are considered; in the author's opinion protein shock therapy is seldom successful in chronic arthritis, and renders subsequent cure by his vaccines more difficult. The contra-indications to the use of peptone as a means of desensitizing patients who have become sensitized to vaccines are mentioned, and the preliminary injection of a minute dose (one two-hundredth) of the vaccine before the real dose is given, in order to obviate sensitiveness, is also described. The results of his treatment are detailed, and among them are included those recorded in his article with a special plate in our issue of November 6th last (p. 834) on the treatment of osteoarthritis of the hip by vaccines.

ORGANIC CHEMISTRY MADE INTERESTING.

WE agree with the views expressed in the preface to Dr. READ'S *Text-Book of Organic Chemistry*[5] that few works on the subject are written in a form to attract the attention and hold the interest of the modern student with his shrewd sense of examination values. Dr. Read is to be congratulated on the effort he has made to break away from the desultory style of presentation to which he alludes. The text of his book is studiously calculated to evoke the interest of the student, the author having recognized the importance of the principle that academic treatment becomes more illuminating when connected with well known facts of technical and economic significance. The book not only contains all the material requisite for the needs of the usual examination courses in science and medicine, but it connects with every item of instruction some piece of information having popular interest. The method renders every page attractive to read and is bound to lighten the burden that falls on mere memory. The volume is large enough for the student entering on the subject, but organic chemistry offers scope in other directions for the application of the author's plan of treatment. Too little is usually done to demonstrate in the proper place the types of reactions which are to become the organic chemist's guide to anticipation of events. He is not generally taught what must happen, for example, to two hydroxyl groups when attached to the same carbon atom, or through what course of intermediate linkages hydrazobenzene undergoes transformation into benzidine. Emulation of the author's plan of treatment in the directions indicated would do much to render organic chemistry a more coherent system of study. As it is, the book deserves the highest commendation. We anticipate that it will be so much appreciated by students, good judges as they are, as to become a popular favourite.

[5] *A Text-Book of Organic Chemistry.* By John Read, M.A.Camb., Ph.D.Zürich, B.Sc.Lond. London: G. Bell and Sons, Ltd. 1926. (Post 8vo, pp. xi + 679; 87 figures. 12s. 6d. net.)

CONCERNING SEX.

Of late there have appeared several small popular books on sex written by people whose only claim to authorship in this subject would appear to be an overwhelming desire to help their fellow women. The extent of the ignorance of well established biological fact and the disregard for scientific method on the part of these authors revealed in such books is appalling. The demand for reliable information concerning the biology and physiology of sex is very widespread, for to the general public sex is still, in spite of the abundant fruits of the last five-and-twenty years of most profitable research, one of the great mysteries. There is no mystery about it really, but only ignorance. It is true that we do not understand as yet all the details of the processes of sex determination and of sex differentiation, but it is equally true that the salient and significant features of these processes are clearly apprehended. The study of the chromosomes and of the hormones has revealed the precision and the wonder of the mechanism concerned. So great has been the advance in knowledge concerning sex that already it is possible to use this knowledge with precision in the actual control of sexuality.

These matters are of interest to the general public, which consists of individuals every moment of whose lives is affected in one way or another by one or more of the various manifestations of sexuality. It is indeed highly important that the general public should be aware of current scientific opinion concerning sex, and it was high time that some professional biologist, well equipped for the task and with a flair for the interpretation of scientific terminology into language understood by the man (and woman) in the home, should enlighten those who desire to make themselves acquainted with the present state of knowledge concerning sex.

Mr. J. R. BAKER[6] has essayed this task. The matter is well chosen and well arranged, the language is sibple, and the facts are adequately, frankly, and rationally discussed. The book may be exceedingly helpful to the general public and to the students of biology and of medicine to whom it is addressed. We say "may be" advisedly, for frankly we are somewhat repelled by the author's method of teaching. We agree that it is necessary to avoid meticulous accuracy and the consideration of elaborate detail in any attempt to disseminate scientific knowledge lest these should disguise the real significance of the general principles of the subject, and that it is often necessary to provide for those who look to others for their creed. But it is highly dangerous to incorporate personal opinion in a body of established fact in such a way as to make them indistinguishable. Mr. Baker has the courage and confidence as well as the enthusiasm of youth. He does not limit his instruction to the biological aspects of this subject, but fearlessly and unrestrainedly simplifies the anthropological and psychological aspects too. Perhaps he knows his public, and gives it that which it needs.

We cannot recommend this book to biological and medical students, however, because they should not be encouraged to listen contentedly to the voice of personal authority. The student should early recognize that humility becomes those who tend the lamps that are lit on the alter of knowledge; that there is more than efficiency in a mechanism, there being also a beauty that provokes respect and even reverence. The book reminds one of a dissected cadaver, very marvellous in a way but definitely dead; the smell of jasmine has given place to the fumes of formalin.

Those who wish to make a quick survey of what is known concerning sex will be well advised to read this book. The opinions expressed will not fail to stimulate thought and discussion. The reader may or may not be attracted, but he will most certainly be grateful to the author for having condensed into so small a space so much that is of importance.

SIR FELIX SEMON.

The Autobiography of Sir Felix Semon,[7] edited by his eldest son, Dr. Henry C. Semon, and Mr. Thomas A. McIntyre, appeals not only to medical men but to a wider audience on account of his varied interests, especially in music and sport, and of his wide acquaintance with royal and other prominent personalities of his time, whose names appear frequently in this memoir. From a professional point of view his career is a striking example of the power of energy and ability to conquer difficulties, for coming as a foreigner to London in 1876 he not only attained great personal success, but helped to raise and establish the status of laryngology, the specialty in which

[7] *The Autobiography of Sir Felix Semon, K.C.V.O., M.D., F.R.C.P.* Edited by Henry C. Semon M.A., M.D.Oxon., M.R.C.P.Lond., and Thomas A. McIntyre. London: Jarrolds, Ltd. 1926. (Med. 8vo, pp. xi + 349; 15 illustrations. 21s. net.)

he was a leader. Further, the volume is adorned by a number of illustrations, his portrait by Sir Hubert von Herkomer and cartoon by Leslie Ward in *Vanity Fair* being especially good.

He was born in Danzig in 1849, and was educated in Berlin; incidentally as a student he fought three duels—two with rapiers, one with pistols. In 1870, when the Franco-German war broke out, he left the study of medicine to serve in the second regiment of the Prussian Uhlan Guards, and went through adventures both exciting and unpleasant. On returning to Berlin he was inspired by Virchow's lucid, if somewhat dryly delivered, lectures and grasp of a colossal subject. The teacher imbued the pupil with the principle that for the science of medicine *unity* of thought is indispensable; this Semon afterwards enforced by insisting on the intimate connexion of laryngology with general medicine. To Traube he acknowledges the debt of being taught, "in his hard and exacting school," to observe accurately and minutely and to interpret such observations with care. In 1874 he left Berlin for a year of post-graduate study in Vienna and London, without, of course, any suspicion that he was really saying good-bye for life to his German home, and would return to Berlin only as a casual hurrying visitor.

On arriving in London he concentrated his work at St. Thomas's Hospital, where he was subsequently on the staff, and his impressions, favourable and critical, of the current medical teaching in London as compared with that on the Continent will be read with interest. An introduction to Dr. (afterwards Sir) Morell Mackenzie, whose "truly wonderful manual dexterity" made a great impression on him, led to regular attendance at the Golden Square Hospital, and after being advised by Richard Liebreich of St. Thomas's to take up a specialty he eventually decided in favour of laryngology as against otology. The early struggle in London is well told, with its strenuous work and interludes of pleasure; it was at this early date that he laid the foundations of what was subsequently known as Semon's law. In 1877 he became engaged to be married. Ten years later, in 1887, he was well established in practice, and for this and other reasons, including loyalty to his friend Fränkel, he declined the offer to become director of the State Policlinic for Diseases of the Throat and Nose at Berlin. The story of the Emperor Frederick's fatal illness, given in considerable detail, has, so the editorial note points out, been somewhat curtailed. Though there is no need to enter into this much discussed matter, it may be mentioned that quite recently Sir Rennell Rodd (*Times*, November 25th, 1926) showed how erroneous is the statement, which indeed in one place (p. 162) Sir Felix Semon repeats—though of what he says elsewhere (p. 148) a different interpretation is possible—that the Crown Princess was solely responsible for Mackenzie's introduction into the case; it was in fact due to the action of Bismarck, who, however, from political considerations, never corrected the opinion universally held in Germany. The thirteen years from 1890 to 1902 marked the zenith of Semon's career, and in 1909 he retired.

The last years of his eventful life were clouded by the war, in which his three sons served, and it is sad that in 1919, when about to be operated upon for supposed malignant disease, he wrote in obvious depression, "The last five years have brought me nothing but worry and misery, and an ever-increasing feeling of bitterness at the ingratitude of my German and some of my British former brother specialists."

NOTES ON BOOKS.

THE last quarterly instalment of the seventy-sixth volume of the *Guy's Hospital Reports*[1] contains twelve articles, of which four are records of cases from the ear and throat department, presided over by Mr. W. M. Mollison, who collaborates in three out of the four reports. The first of these is a case of spontaneous expulsion by coughing of a pneumolith containing much calcium and possibly a calcified tuberculous bronchial gland. The second is on two cases of apparent cure by operation for neuroblastoma of the ethmoid and for carcinoma of the antrum respectively. Dr. J. F. Carter Braine and Mr. Grant Massie report on the results of treatment of 722 cases of mammary carcinoma admitted into the hospital during the thirteen years ending August, 1922, and give eight conclusions; there seems to be little or no connexion between the histology of the growth and post-operative survival; of the 388 verified cases 54 per cent. were alive three years after operation, 21 per cent. after six years, and 11.5 per cent. after nine years. Dr. A. F. HURST describes a case of the Plummer-Vinson syndrome (spasm of the [illegible]cter with anaemia and splenomegaly), [illegible] in 1921 by Plummer and Vinson of [illegible] parative study of the development and physiology of identical twins who had always been under the same environmental conditions, made by Dr. G. P. Crowden, showed their psychological, anatomical, and physiological development to be similar; they were once accused of cheating in an examination because they made the same mistake in the same problem, but their characters were cleared by their form-master, who reported that they sat at opposite ends of the examination hall. Mr. Ralph Brooke and Mr. Frank Cook discuss secondary pelvic contraction, in which an actual diminution in the size of the pelvis results directly or indirectly from antecedent confinements which may have been uneventful. In a preliminary observation on the treatment of nephritis with oedema by large doses of alkalis Dr. A. A. Osman shows that it has some prophylactic value in preventing the incidence of nephritis after scarlet fever, and that it is of use in the treatment of nephritis with oedema.

Dr. BELFRAGE, in introducing his book *What's Best to Eat?*[2] evidently feels the need to apologize for adding another to the list of books on food. He excuses himself on the ground that the relation between disease and faulty habits of diet cannot be too often or too forcibly pointed out. The book has a foreword from Professor E. V. McCollum of the Johns Hopkins University, who tells us in italics that "many and serious as are the problems confronting Europe and America . . . none is more important than the application of the science of nutrition in the daily life of the people." Sir William Arbuthnot Lane, to whom the book is dedicated, is quoted on the wrapper as saying that "the deeper one digs into it the more valuable, instructive, and inspiring are its contents." Dr. Belfrage has a good deal to say of infection from the bowel, particularly from that "sewage chamber" the colon. The general impression we get from the book is that Dr. Belfrage is a most industrious collector of information and opinion on diet, and that the most useful part is the "practical supplement," by Miss LUCY YATES, containing recipes for various dishes.

To encourage the use of smokeless fuels for domestic purposes the Smoke Abatement League has published a book on *Home Fires without Smoke*.[10] It has two editors, Mr. CYRIL ELLIOTT and Miss MARION FITZGERALD. The former modestly confines himself to the preface; of the extent of the latter's effort no evidence is forthcoming. In a foreword Sir NAPIER SHAW, after quoting Carlyle's prophecy of the "hero as a man of letters," expresses the opinion that it is on the "hero as a man of gas" that we must fix our minds for smoke prevention on a large scale. The contributors to the volume, however, do not limit us so strictly. Thus Dr. Margaret Fishenden writes on the use of coke for sitting-rooms, central heating, hot water, and cooking. She allows us to use some coal, provided we begin the fire with the previous day's cinders and give the coal plenty of air. Mr. Goodenough, executive chairman of the British Commercial Gas Association, lauds the advantages of gas; he thinks that gas fires can be made beautiful and so artistic as to harmonize with the room. Mr. Masters favours a liberal use of electricity, but advises a coke furnace and boiler for hot water in winter. Two other contributors, as a result of visiting one hundred and fifty housewives, conclude that the kitchen range is out of date, but they spread their sympathies over coke, gas, and electricity impartially; they plead for scientifically conducted cost and utility tests. The book should be useful to those in search of, or anxious to improve, a home.

The *Transactions* of the sixth biennial congress of the Far Eastern Association of Tropical Medicine, held in Tokyo during the latter half of October, 1925, are being published by the Kyorinsha Medical Publishing Company. The first volume has now been received; it contains 148 scientific papers, in addition to the presidential address of Baron S. Kitasato.

NINETY-FIFTH ANNUAL MEETING
of the
British Medical Association.
EDINBURGH, 1927.

Edinburgh Castle.

THE ninety-fifth Annual Meeting of the British Medical Association will be held in Edinburgh next summer under the presidency of Sir Robert Philip, M.D., LL.D., honorary physician to the King in Scotland, who will deliver his address to the Association on the evening of Tuesday, July 19th. The scientific and clinical work of the meeting will occupy, as usual, the three following days, and on this occasion it will be divided among twenty-one Sections. The names of the Presidents of Sections were published in the SUPPLEMENT of December 4th last; the full list of officers, together with the provisional programme of scientific business and other details of the arrangements for the Annual Meeting, will appear in later issues. The Annual Representative Meeting, for the transaction of medico-political business, will begin on Friday, July 15th. On the last day of the meeting (Saturday, July 23rd) there will be excursions to places of interest in the neighbourhood. We print below the second of a series of descriptive and historical articles on the Scottish metropolis and its relations with the science and practice of medicine. The first article, published on December 4th (p. 1067), dealt with old Edinburgh and the beginning of the Edinburgh Medical School.

THE EDINBURGH MEDICAL SCHOOL FROM 1726 TO THE MIDDLE OF THE NINETEENTH CENTURY.

AFTER the formation of a medical faculty in the Tounis College, the University of Edinburgh, as it now began to be called, commenced to attract students from places outside Edinburgh. The increasing popularity of medical teaching at this school may be roughly gauged by the numbers of graduates in the faculty of medicine during the century following the foundation of the medical faculty. Taken by decades after 1726, the numbers of graduates were as follows: 16, 20, 108, 79, 170, 242, 330, 469, 586, till for the decade ending 1825 the numbers reached 1,071. These figures do not represent all the persons studying medicine at Edinburgh, because in the early days it was more usual to obtain a licence to practise from the College of Surgeons or to graduate at a foreign university, while the fashion of taking a University degree in Edinburgh gradually increased.

The early faculty was composed of Alexander Monro (anatomy), Andrew St. Clair and John Rutherford (institutes of medicine and medicine), George Preston (botany), Andrew Plummer and John Innes (chemistry and medicine), and Joseph Gibson (midwifery). It may be pointed out that Joseph Gibson's appointment was the first professorship in the subject of midwifery in the United Kingdom. Dr. Archibald Pitcairne, Sir Robert Sibbald, and some of the others who had been concerned towards the end of the seventeenth century in the project of founding a medical school at Edinburgh and in obtaining a charter for its College of Physicians, were men of European reputation, but the group forming the faculty of medicine in 1726 appear to have busied themselves chiefly with practice and teaching. Robert Whytt, who in 1747 succeeded St. Clair and Rutherford as professor of institutes of medicine and of medicine, attained a considerable degree of celebrity beyond the confines of Edinburgh. Great public interest was taken in the early years of the eighteenth century in the search for substances which would dissolve a calculus in the bladder. Whytt in 1743 had published an "Essay on the virtue of lime-water and soap in the cure of the stone," which had attracted considerable attention, and, largely as the result of this, he was elected to the chair. An important scientific result of these researches in regard to the properties of alkalis was that of Joseph Black, who in 1754 was led by them to his elaborate series of "Experiments upon Magnesia Alba, Quicklime, and other Alcaline Substances," in the course of which he discovered the first known gas, which he called "fixed air" (carbon dioxide). Whytt busied himself for some years after his appointment chiefly with physiological researches. The publication of some of these brought him into conflict with Albrecht von Haller, the great hierarch of physiology, with whom Whytt had a considerable correspondence. In his observations upon hysterical disorders, Whytt appears to have anticipated the modern conception of referred pain, and he also did much to localize the seat of different reflexes in the spinal cord. He was the first person to give a clear description of tuberculous meningitis or, as he called it, "dropsy of the brain," which is still described according to the three stages into which Whytt divided its symptoms. An interesting point in connexion with this disease was that the foramen connecting the lateral ventricles was observed dilated in a case dying from hydrocephalus which Whytt had seen in consultation with Monro (*secundus*) in the year 1764. This opening has subsequently been known as the "foramen of Monro."

WILLIAM CULLEN.
(After an engraving by Ridley.)

Among the early professors, William Cullen has attained

the most lasting fame. Following the usual practice of the time, Cullen had served an apprenticeship of two years to a Glasgow surgeon, and had studied for six months at the newly instituted faculty of medicine in Edinburgh. After some time spent in country practice he had removed to Glasgow, where he had delivered lectures on medicine and chemistry, and in 1755 he had joined Professor Plummer, then in failing health, as joint professor of chemistry at Edinburgh. As chemistry did not satisfy his medical ambitions, in 1757 he undertook to deliver clinical lectures in the Royal Infirmary of Edinburgh. This type of lecture upon the cases of patients in the hospital had been commenced by Professor John Rutherford in 1748 on the model of lectures which he had attended in the hospital at Leyden. Clinical lectures formed a new idea in medical teaching, which had not up to this time been introduced in other British schools, and their development formed one of the fundamental characters of the early Edinburgh Medical School, upon which its reputation was built up. In 1766 Cullen became professor of the institutes of medicine (physiology), and in 1768 an arrangement was effected with Dr. John Gregory, by which Gregory and Cullen gave alternate courses in the practice of medicine. Cullen became sole professor of medicine on Gregory's death in 1773, and it is an interesting fact, compared with the tendency in present-day appointments, that Cullen, the greatest figure in Edinburgh medicine, was 63 years of age at the time when he entered upon the duties of this chair. Cullen had developed a large, lucrative, and aristocratic consulting practice in Scotland, but his chief influence on the public mind was exerted by the great attraction that he exercised in bringing students from a distance through the clearness of perception, sound reasoning, and judgement displayed in his lectures. His chief published works are *A Treatise on Materia Medica*, *First Lines on the Practice of Physic*, and his *Nosology*, a small pamphlet which aimed at a rigid classification of diseases by their symptoms on the same arbitrary principle which Linnaeus had adopted for classifying plants by classes, orders, genera, and species. Cullen's pre-eminent position in the Edinburgh school of his day is indicated by a sentence in a letter to him from John Hunter in October, 1785, regarding Cullen's project of retirement, in which Hunter says, "I tremble for Edinburgh when you determine giving her your assistance."

ALEXANDER MONRO (*secundus*).
(After the engraving by James Heath from Raeburn's portrait.)

During Cullen's student days in Edinburgh he had joined himself to a private debating club of students founded in 1734, from which the Royal Medical Society of Edinburgh subsequently developed. The society held its meetings in a tavern, but at a later date (1774) Cullen exerted himself to obtain a hall of meeting for this society, and in 1778 was instrumental in obtaining its incorporation by Royal Charter. The society existed as a meeting-place of students for exchange of views and criticism of the teaching they received, and it has undoubtedly played a very large part in the development of the Edinburgh Medical School, in which it still continues to enjoy a flourishing existence. The keenness with which medical theories were debated is indicated by one of the old laws, which enjoins that if any personalities shall have taken place the president in the chair shall obtain an assurance from the members concerned that no hostile meeting will afterwards take place in consequence. One of the presidents in the year 1760 was John Brown, who later became an extra-mural lecturer, and between whom and Cullen, about the year 1778, arose a great deal of trouble in regard to the nature of disease. Brown introduced a system, which was essentially the old Methodist idea revived, that disease is due to too great laxity or too great stringency of the particles of the body. This Brunonian theory, which was easy to understand and required very little knowledge of medicine, appealed strongly to the members of the Royal Medical Society, and subsequently spread all over Europe.

One of the most important contributions to science in the early days of the Edinburgh medical school was the discovery of "fixed air" by Joseph Black, who became professor of chemistry and medicine in 1776. Black was also one of the earliest adherents in Britain to the antiphlogistic theory of combustion subsequently advanced by Lavoisier. He was followed in 1799 by Professor Thomas Charles Hope, who found out numerous important facts in physical and chemical science, being particularly celebrated for his discovery that water attains its maximum density several degrees above freezing-point and expands as it solidifies. Another advance in chemistry was made by Daniel Rutherford, an uncle of Sir Walter Scott, appointed professor of medicine and botany in 1786. In 1772 Rutherford presented an M.D. thesis entitled "De aere fixo dicto, aut mephitico," in which he dealt with Black's "fixed air," and pointed out that after the "fixed air" was removed by caustic lye there still remained a gas which extinguished flame and life no less than before. This was the discovery of nitrogen.

Among the pupils of Cullen were many students from the American colonies. One of these was John Morgan, who graduated at Edinburgh in 1762, and in 1775 was appointed Director-General and Physician in-Chief to the American Army under General Washington. He was succeeded in this position in 1777 by William Shippen, another Edinburgh graduate, who held the Director-Generalship for twenty years, and later was largely instrumental in organizing the medical department of the University of Pennsylvania. Still another Edinburgh graduate was Benjamin Rush, who subsequently became professor of institutes of medicine in the University at Pennsylvania and one of the signatories of the Declaration of Independence. All these men were of highly contentious disposition, and this may possibly have provoked the remark made by Benjamin Franklin in his autobiography that a disputatious turn "is apt to become a very bad habit, making people often extremely disagreeable in company by the contradiction that is necessary to bring it into practice. . . . Persons of good sense, I have since observed, seldom fall into it, except lawyers, university men, and men of all sorts that have been bred at Edinborough."

The professoriate in the latter half of the eighteenth century, which included several men of marked individuality, appears to have been distinguished by singular pugnacity. The outstanding public figure of the school after the death of Cullen was probably Dr. James Gregory,

professor of medicine from 1790 to 1821. His name is still a household word owing to the powder containing rhubarb, magnesia, and ginger, which he introduced. He had the somewhat eccentric habit of wearing his hat throughout his lectures, and his three great therapeutic measures appear to have been antimony, blistering, and blood-letting. Owing to the fact that students were now flocking to Edinburgh from all parts of the British Isles and the colonies, Gregory's doctrines became universally employed, and he, more than any other man, was responsible for the great proportions to which blood-letting attained in the early years of the nineteenth century. Lord Cockburn, who admirably summed up the characters of many of the worthies in the Edinburgh of his day, says of Gregory:

"He was a curious and excellent man, a great physician, a great lecturer, a great Latin scholar and a great talker; vigorous and generous; large of stature and with a strongly powerful countenance. The popularity due to these qualities was increased by his professional controversies, and the diverting publications by which he used to maintain and enliven them. The controversies were rather too numerous; but they never were for any selfish end, and he was never entirely wrong. Still, a disposition towards personal attack was his besetting sin."

His disposition towards personal attack led him on one occasion to terminate a controversy with Professor James Hamilton regarding the authorship of a pamphlet by beating the latter with his walking-stick. For this Professor Hamilton brought a lawsuit and received £100 by way of damages. Gregory is said to have remarked in paying the damages that he would willingly pay double for another opportunity. Hamilton, however, although eminent in his professional branch of midwifery, was a notorious litigant, and had lawsuits also with Professors Andrew Duncan and Thomas Charles Hope. Hope had used regarding Hamilton the words of Dr. Samuel Johnson on a like occasion, "The fellow lies and he knows that he lies." This, being reported to Hamilton, caused a lawsuit, with a verdict in favour of Hamilton of ¼d. damages. The Edinburgh public was greatly delighted with the legal proceedings, and Hope received a shower of letters from his friends enclosing farthings, one of which he sent to Hamilton, demanding a receipt.

ANDREW DUNCAN.
(From the portrait by Sir Henry Raeburn in the Royal College of Physicians, Edinburgh.)

Andrew Duncan was professor of institutes of medicine from 1789 to 1819, and was celebrated for his pleasantness of manner and kindliness of disposition, which had gained for him the sobriquet of "the smiling boy." Duncan had a hobby for founding convivial societies, some of which, notably the Harveian and Aesculapian Societies, are still extant. Of more importance, however, in this direction were his activities in obtaining Royal Charters for no fewer than four societies, and founding the Medico-Chirurgical Society of Edinburgh in 1821. He is still remembered as the man who was so much impressed by the sordid death of Robert Ferguson, the poet, in the evil surroundings of the city Bedlam that he exerted himself to bring about the founding of the Royal Asylum for the Insane at Morningside in 1813, one of the earliest asylums instituted for the humane treatment of the mentally diseased in Great Britain. Professor Andrew Duncan was succeeded in 1819 by his son, Andrew Duncan jun., who ten years before that time had been made professor in the newly established chair of medical jurisprudence or forensic medicine, this chair having been the first of its kind to be instituted in Great Britain. The younger Duncan was transferred for a second time in 1821 to the chair of materia medica, which he held till 1832, when he was succeeded by Sir Robert Christison.

In 1821 Dr. William Pulteney Alison was made professor of the institutes of medicine, and in 1842 he was transferred to the chair of medicine. Alison busied himself especially with practical activities and treatises. The latter were mainly concerned with the amelioration of the Scottish poor, and from the beginning of his medical experience he had been deeply impressed with the manner in which poverty and unfavourable social conditions assisted in the spread of disease. His treatise *Observations on the Management of the Poor in Scotland and its Effects on the Health of great Towns*, issued in 1840, was largely responsible for the Commission of Inquiry and the Poor Law Act of 1845, which embodied most of what he had striven for. His work was an important precursor of much of the social legislation at the present day. He was appointed President of the British Medical Association at its annual meeting in Edinburgh in 1858. A peculiarity displayed by him was a singular habit of scarcely ever seeing a patient without writing a long prescription for a new bottle of medicine. It is recorded that as he visited his wards several times a day the bottles tended to accumulate, till neither the patient nor the nurses, nor the professor himself, knew precisely what was being taken and what was not.

The chair of anatomy remained in the family of Monro for the long period of 126 years. Alexander Monro (*primus*) had been appointed to the chair of anatomy in 1720, and was succeeded by his son of the same name in 1758. Alexander Monro (*secundus*) became celebrated both as a teacher and for the investigations which he carried out. It is interesting that none of the great works on which his reputation rests was published till after he was 50 years of age. These included *Observations on the Structure and Functions of the Nervous System*, *The Structure and Physiology of Fishes*, a description of the *Bursae Mucosae of the Human Body*, and a treatise on *The Brain, Eye, and Ear*. The experiment of appointing a son to succeed his father, which had proved so successful in the case of the first two Monros, was again tried by Monro (*secundus*) when in 1798 he petitioned the Town Council to appoint his eldest son as his successor. Alexander Monro (*tertius*) held the chair till 1846, but without the success which had attended the efforts of his father. A recent writer says of him:

"He used to read his grandfather's lectures, written about a century before; and even the shower of peas with which expectant students greeted his annual reference 'When I was a student in Leyden in 1719' failed to induce him to alter the dates."

Charles Darwin, the naturalist, who studied medicine at Edinburgh from 1825 to 1827, in his autobiography gives him the following testimonial: "Dr.——made his lectures on human anatomy as dull as he was himself and the subject disgusted me." During the tenure of the chair by the third Monro, several brilliant anatomists conducted classes outside the University. It is a curious fact that though the first two Monros lectured on surgery, neither was an operating surgeon and the second was a consulting physician with a large practice.

In 1786 John Bell, becoming a Fellow of the College of Surgeons, saw a great chance, and he, assisted by his brother Charles, taught anatomy for thirteen years. It is no exaggeration to say that they founded the subject of surgical anatomy. So successful were Bell's anatomical classes that a combination led by Professor Gregory was formed against him. The attack opened with a pamphlet warning students against attending Mr. Bell's lectures, and the dispute was conducted on both sides with great personal abuse. Gregory's party, however, finally secured John Bell's exclusion from the infirmary, and Bell therefore ceased to lecture in 1799, confining himself to surgical practice, in which for about twenty years he was the leading operator and consultant throughout Scotland. Charles Bell removed to London in 1804 and took over the old Hunterian Anatomical School in Windmill Street, where he spent thirty-two busy and eventful years. The Edinburgh school made some amends to him by offering him the chair of surgery in 1836 when the Gregory faction had passed away, and Sir Charles Bell occupied this chair for the last six years of his life.

Another extra-mural lecturer on anatomy was John Barclay, a "stickit minister" of the Church of Scotland, who was an assistant to John Bell and began to teach on his own account in 1797. Barclay's dissecting-rooms were at No. 10, Surgeons' Square, and here he was assisted and finally succeeded by Dr. Robert Knox, who obtained an unfortunate notoriety in connexion with the Burke and Hare murders in 1828. Burke and Hare were two debased Irishmen resident in Edinburgh, who conceived a scheme of supplying bodies for the dissecting-rooms at less trouble and danger to themselves than could be effected by the methods of body-snatching commonly followed by the "Resurrectionists" of the time. Their method was to entice friendless people into their house in the Westport, stupefy them with drink, and thereafter stifle them and sell the bodies to the porters of the various anatomy rooms. At least sixteen people were thus done to death before Burke and Hare were apprehended, and the last of these bodies being found in Knox's rooms, the public animus was therefore naturally directed first at him. This incident led ultimately to the Anatomy Act of 1830, with better arrangements for the supply of material for the teaching of practical anatomy.

The subject of surgical anatomy introduced by the Bells was revived by Robert Liston, with James Syme as his assistant, towards the close of the second decade in the nineteenth century. Liston and Syme between them carried on an anatomical class with ever-increasing success. Other distinguished extra-mural teachers of anatomy at this time were John Lizars and William Fergusson and, at a slightly later date, William Sharpey, who, during his Edinburgh period discovered the cilia possessed by some mucous membranes, and Allen Thomson, who with Dr. Martin Barry made many of the fundamental discoveries in embryology. Monro (*tertius*) was succeeded in 1846 by John Goodsir, one of the earliest advocates of the importance of the cell as a centre of nutrition. To him Virchow recognized his indebtedness by dedicating his *Cellular Pathologie* to Goodsir as "one of the most acute observers of cell life."

Sir Charles Bell was succeeded in 1842 in the chair of surgery by Professor James Miller, a great orator, the author of a successful work on *The Principles and Practice of Surgery*, and subsequently one of the collaborators with Sir J. Y. Simpson in the introduction of chloroform. A chair of clinical surgery had been founded in 1803 by King George III, and endowed with a stipend of £50 per annum. The first incumbent was James Russell, who had been selected by the managers of the Royal Infirmary in 1800 to be one of six surgeons who should act upon the staff in place of a former agreement dating from 1738, that all members of the Incorporation of Surgeons should act in rotation as operators in this institution. After acting as professor for thirty years, Russell relinquished the chair of clinical surgery in 1833, and James Syme was elected as his successor. There had been a great contest between Liston and Syme for the chair. Both were expert anatomists and skilful surgeons, but each was by nature contentious. Early in their career they had been demonstrators in Barclay's dissecting-rooms, and they had conducted a course of anatomy and surgery together, while each assisted the other in his private operations. Gradually, however, a quarrel arose and acrimonious wrangling in public took the place of their former friendship. On account of Liston's high-handed attitude towards the other surgeons he had been excluded by the managers of the Royal Infirmary in 1822 from again entering that institution, and he was not reappointed until 1827. In 1829, when Syme applied for the surgeonship of the infirmary, the managers declined to appoint him, fearing that the feud between him and Liston might lead to disturbing scenes in the presence of the students. In 1833 Syme defeated Liston, after a bitter contest, for the chair of clinical surgery in the University, and in 1835 Liston accepted the offer of the chair of clinical surgery at University College, London. Some of the most brilliant operative work of these two surgeons was performed during the period of their exclusion from the Royal Infirmary.

The two greatest figures in medicine at Edinburgh in the forties of last century were probably Sir Robert Christison and Sir J. Y. Simpson. Professor Hughes Bennett made the discovery of leucocythaemia in 1845, but his chief activities fall into the latter half of the century. Christison had been professor of medical jurisprudence from 1822 to 1832, when he was transferred to the chair of materia medica, and he had been one of the pioneers in toxicology and pharmacology—sciences which had come into existence in France during the early part of the century. His *Dispensatory*, published in 1842, prepared the way for the first *Pharmacopoeia* of Great Britain and Ireland, issued by the General Medical Council under his superintendence in 1864. He acted as President of the British Medical Association at the Edinburgh Meeting in 1875. Several important alkaloids were first isolated by him and the therapeutic uses of others were discovered. A simple method of extracting morphine from opium had been discovered by another Edinburgh man, Dr. William Gregory, in 1831, and this paved the way for the discovery of many other alkaloids. Sir James Young Simpson, who became professor of midwifery at Edinburgh in 1840, made many additions to his own branch of medicine as well as valuable contributions to the literature and history of medicine. His name is especially associated with the introduction of chloroform, and, indeed, with fighting the battle against prejudice for the use of anaesthetics generally in Britain. Sir Humphry Davy, about half a century earlier, had suggested nitrous oxide gas as an anaesthetic, but its use appears to have been practised for the first time in 1844 by Dr. Wells at Hartford, Connecticut. Dr. Morton of Boston, U.S.A., had introduced a new era in anaesthetics in 1846 by extracting a tooth without pain whilst the patient was breathing sulphuric ether, and very shortly after had tried ether in a number of surgical operations. In January, 1847, Simpson applied sulphuric ether for the first time as an anaesthetic in midwifery, and in November, 1847, at Edinburgh, discovered the anaesthetic effects of chloroform, which soon superseded ether and extended rapidly and greatly the practice of anaesthesia in surgery and midwifery.

These were some of the chief figures and activities which enhanced the fame of the Edinburgh Medical School in pre-Listerian times. During Syme's tenure of the chair of clinical surgery he was visited by Joseph Lister, who became so much attracted by Syme's personality that he stayed on with Syme, first as house-surgeon and later as an extra-mural lecturer on surgery and assistant surgeon to the Royal Infirmary, and in 1856 married Syme's eldest daughter, Agnes. Syme was succeeded in the chair by his greater son-in-law in 1869.

British Medical Journal.

SATURDAY, JANUARY 1ST, 1927.

MEDICAL CHARITY.

No man knows with certainty what awaits him in the coming year, but to one section of the medical profession the future is definitely clouded and dismal. Many of our brethren, overtaken by sickness or incapacity, can only look forward to the continuation of an existence deprived of those little amenities of life which to the cultured man are so important as to rank almost as necessities. Some, even worse off, have nothing to expect but a life of penury and privation, not only for themselves, but, what is even harder to bear, for those whom it has been their life's aim to protect from care.

The amount of distress among members of our profession is but faintly realized, and always comes as a shock to those who look into the matter closely for the first time. A glance at the list of cases (published from time to time in the JOURNAL) which are helped by the Royal Medical Benevolent Fund reveals the dire straits in which many doctors and their dependants are placed. It is distressing to think of the wives and daughters of medical men compelled to eke out their meagre incomes by doing the work of charwomen or seamstresses. And while many such cases have been discovered, it is known that there are many others where brave women shoulder their burden alone, too proud and too independent to ask for help.

Owing to lack of money, the Royal Medical Benevolent Fund is only able to grant absurdly inadequate sums (often a mere £12 per annum) in relief of such cases as we have mentioned, and some of the recipients have been forced to augment this slender assistance by application for the old age pension. The only way to remedy this state of affairs is by regular and systematic support, and this is best done by contributions to the Charities Trust Fund, established by the British Medical Association, which allocates the sums at its disposal to the existing professional funds, including the Royal Medical Benevolent Fund, the Epsom Foundation, and the Charles Hastings Fund. It is now a year and a half since the Representative Body set up a Charities Committee, with the object of stimulating the profession at large to give better support to the existing medical charities; but although a considerable number of doctors are liberal subscribers to these funds, there are many others who do not yet realize how pressing is the need. To the latter we would commend the exercise of the virtue of "charity"—not in the narrow sense of perfunctory almsgiving, but rather as an expression of goodwill towards their brethren in need, and of thankfulness that their own lines have fallen in more pleasant places. Many who have won an established position must have had moments in past days when the spectre of ill health or early incapacity caused grave forebodings, when the plans they had made for the careers of their children and the future welfare of those near and dear to them seemed doomed to go astray. An opportunity now comes to them to help those whom Fate has treated less kindly. The claims of the professional charities should appeal no less to the younger generation of doctors, for it will assuredly give them a sense of security to know that there are substantial resources to which they can turn if misfortune comes their way. Furthermore, we would point out that, a Charities Trust Fund having been set up by the Representative Body, it behoves every member of the British Medical Association to do his utmost to see that the Fund achieves its purpose. To bring this about much hard work must be done by the charities committees of the local Divisions, and a circular will shortly be sent out by the Head Office with suggestions for the best methods to be pursued.

It is surely an anomaly that the profession which is by general consent the most philanthropic of all should make such miserable provision for its needy members. We are well aware of the many calls made on the profession, but we venture to suggest that the first call to be considered is the cry of distress from our unfortunate colleagues and their families who, through no fault of their own, have fallen by the way. We believe that in years to come the Association will be able to look back with just pride on the inception of the Charities Trust Fund as one of the most important of the landmarks in its history.

> "In Faith and Hope the world will disagree,
> But all mankind's concern is Charity."

LEGISLATION IN 1926.

THE disturbance of parliamentary business by the general strike and the mining dispute has, in the long run, helped rather than hindered ordinary legislation, and the session of 1926 is noteworthy, not solely because the supremacy of Parliament was vindicated against the challenge of the general strike, but also because of the passage of sixty public Acts, including seven or eight of direct medical importance. The industry of the Ministry of Health in seeking to overtake arrears of such legislation has, indeed, aroused criticism from some supporters of the Government, and when, at the close of the session, the Mental Deficiency Bill was challenged by two prominent members of the Opposition, the Prime Minister did not ask his followers to force it through.

Happily, it can be said that the Acts of medical interest which did pass were thoroughly discussed, but did not arouse party controversy. There are still evidences from time to time that back-bench members of both sides of the House are apt to develop a layman's jealousy of the medical profession. This was visible at the opening of the session in the demands for alteration in the constitution of the General Medical Council, and at its close in the protest by Labour members against the increase of doctors' fees under the Coroners Act. The first misunderstanding was removed by the action of the Government in adding a lay member of Parliament to the General Medical Council. Since that appointment there have been scarcely any instances where questions were put to score off the medical profession or to cast doubts on its motives. Sceptical questions about vaccination have been infrequent, and several debates —for example, those on the Smoke Abatement Bill— have revealed appreciation of the importance of public health. In part for party reasons, this appreciation was prominently displayed in the discussion on that section of the Economy Act which reduced the State contribution to National Health Insurance. It is noteworthy that, despite the prolongation of the mining stoppage through seven months, no convincing evidence was brought before the House of Commons to show there was widespread malnutrition in the

coal-fields, or any increase in the death rate there, which could be attributed to destitution. The same is true of the country generally, although the number of persons registered as unemployed rose from 981,877 on April 26th to 1,612,700 on May 17th, apart from those directly involved in the coal dispute. The number has remained high since, but tended to fall during the autumn.

In the later part of the year the occurrence of infantile paralysis and the continued outbreaks of encephalitis lethargica have been brought before the House by many questions, which have elicited information as to the incidence of these diseases in various areas. Recognition of the dire sequels of encephalitis lethargica was the cause which predisposed the House of Commons to give an easy passage to the Mental Deficiency Bill in its early stages. The last moment opposition to it resulted from a concurrence of doubt about the definition of mental deficiency with the old jealousy for the liberty of the subject, and a feeling on the Conservative side that too much legislation was going through. This last feeling may affect Mr. Chamberlain's plans, as Minister of Health, for next year, and is likely to cause a further postponement of the Factories Bill, which was promised for the session now closed but never debated. Mr. Chamberlain appears, however, to have Cabinet sanction for proceeding with the Poor Law Reform Bill, the draft of which has already been circulated to local authorities. He is also expected to bring in a bill carrying out the recommendations of the National Health Insurance Commission. The recommendations of the Lunacy Commission, presented in the summer, await the Government's consideration, and action will have to be taken eventually on the report of the Select Committee on Nursing Homes. This committee examined many witnesses during the early months of the session, and its report forced public attention to undesirable features of the present system. One special aspect of the matter—that of the regulation of maternity homes—Parliament dealt with by general consent in the Midwives and Maternity Homes Act.

During the session Mr. Chamberlain secured the passage of an Act somewhat increasing the powers of local authorities to deal with the smoke nuisance, and of another enabling the Minister of Health to supersede spendthrift boards of guardians by commissioners. He also obtained sanction for reductions in the housing subsidies from next autumn. The Births and Deaths Registration Bill originated with a private member, as had previous versions in past sessions. That it became law this year was partly due to the active support of the Ministry of Health. Credit for the carrying of this Act, of the Coroners Act, and of the Smoke Abatement Act is also due to the Parliamentary Medical Committee. This group is now undoubtedly a power in the House of Commons, helping to shape both legislation and opinion, and has been helpful to the British Medical Association in various directions. The chairman of the committee, Dr. Fremantle, has also been chairman of the Conservative party's Committee on Health and Housing. Tuberculosis in the fighting forces and the training of midwives are matters which individual members have kept before the House of Commons. The committee as a body circulated a memorandum to members generally on social hygiene. Among the decisions of the House of Commons on general policy which are important to medical practitioners is one in the Finance Act whereby, from 1927-28, the system of taxing income on a three years' average is to be abolished. Regulations greatly to diminish the use of preservatives in food come into operation to-day and at various later dates. Clean milk regulations came into operation on October 1st.

Medical matters have not been prominent in the discussions of the House of Lords, but the Earl of Balfour, as Lord President of the Council, has been concerned with the promotion of research, and is now not only chairman of the Medical Research Council, but also head of a new Cabinet committee to co-ordinate and extend civil research of all kinds.

To sum up the session of 1926 from the medical aspect, it has been one of useful results in matters of detail, but it has given no evidence that Parliament yet realizes that money is never more profitably expended than in improving public health, nor much evidence that Ministers and other members of Parliament are really ready to accept medical opinion as their guide on health subjects.

DEAD BIRTHS AND NEO-NATAL DEATHS.

THE report of the Medical Research Council on dead births and neo-natal deaths, of which we publish a review at page 32, marks the conclusion of a number of detailed investigations carried out since 1919 under the auspices of the Council at various centres throughout Great Britain, in order to determine the incidence of the causes of foetal and neo-natal death. The outstanding features of the report have been referred to in our review, and we only wish here to emphasize what had already been made abundantly clear by the published papers of the workers concerned—namely, that a large proportion of foetal and neo-natal deaths are preventable by adequate ante-natal supervision and by skilled obstetric treatment when active intervention is necessary in the interest of mother and child. Fully one-half of the total deaths were due to the various complications of labour and the toxaemia of pregnancy (including under the latter term only albuminuria and eclampsia), and should therefore be almost entirely preventable. Further, it should be remarked that the infants lost through complications of labour are often just the healthiest and best developed, and therefore those which the State can least afford to lose; and they are lost because they are large, and therefore cause more or less difficulty in labour. In this respect the report is a confirmation of the wisdom of the teaching of that pioneer in ante-natal care the late Dr. J. W. Ballantyne of Edinburgh, who for twenty-five years before his death in 1923, and frequently in the columns of this JOURNAL, insisted on the necessity for ante-natal supervision of all expectant mothers. Instruction in the methods of ante-natal diagnosis and treatment is now looked upon as an essential part of the training of the medical student and midwife, largely as a result of his work, and there can be no doubt that within a few years, when the effects of this new teaching become apparent in medical practice, a great diminution in foetal and maternal mortality will result.

But ante-natal care is not an end in itself, and the report does well to emphasize the additional need for skilled obstetric care and for increased hospital accommodation. "The larger maternity hospitals with their staffs of skilled obstetricians could surely spread their aid and influence over a larger area than they do at present if only the importance of the work were fully appreciated." Some of those concerned in teaching foresee the need for careful organization. The present tendency to provide a large number of small hospitals

throughout the country, each of which serves its particular district, is highly to be commended, and it can hardly be doubted that the services of skilled obstetricians from the large centres will be obtained for treatment of the more difficult cases. This is an advance, and may be expected to bring about a reduction in foetal and maternal mortality, but it is thought that unless the whole organization is well worked out in consultation with the local hospitals there may be a risk of the maternity hospitals in the large teaching centres being starved of material for instruction of students or for research. If cases of eclampsia, for example, are, as it were, held up at the district hospitals, it may well be that a student will pass through his training in obstetrics, lasting three months or even longer, without ever seeing a case. The district hospitals cannot be expected to have a registrar, and it will hardly be possible to keep such accurate records as in the large centres, where notes are kept and standardized under the supervision of such an officer. As to research, it is unlikely that laboratory facilities will be available in the smaller hospitals. There is the question also of puerperal fever, both from the point of view of treatment and of education. In large hospitals not only can the best treatment be applied, but ample laboratory facilities are, or ought to be, available for their bacteriological investigation.

The problem is no doubt one of serious importance which will have to be faced very soon by all who are responsible for the teaching of midwifery in the medical schools. Should present tendencies continue it is conceivable that their activities will in time be confined to teaching the theory of midwifery and the conduct of a normal labour, leaving the student to acquire a practical knowledge of the complications of labour and of the methods of dealing with them after he commences practice.

The Medical Research Council is to be congratulated on its wisdom and foresight in organizing this investigation and carrying it to a successful conclusion. It is to be hoped that the workers who took part in it will, now that the main object has been achieved, continue their investigations into some of the many still unexplored fields of ante-natal pathology—a task for which the experience gained in the present research must have well qualified them.

UNDULANT FEVER AND THE ABORTION BACILLUS.

THE obviously close relationship between bovine abortion and undulant fever is a subject which is receiving the increasing attention of bacteriologists and clinicians in many parts of the world. We have on several occasions drawn attention to the question, and repeatedly urged the necessity for increased research into the possibilities of *Bacillus abortus* in human medicine, for the organism, from its very ubiquity, has great potentialities as a factor of disease in all countries where milk is consumed. Recently several cases of apparent infection of human beings by the bovine bacillus have been recorded. Huddleson[1] has reported a case in a graduate who became ill when working with cultures of the bacillus, and in whom an irregular fever was noticed for over a year. Two students in the same laboratory, working with the same bacillus and drinking milk which proved to be infected, also contracted the disease. Organisms which were identical with *B. abortus* were isolated from their blood. Carpenter and Merriam[2] report two similar cases in which the bacillus was isolated. The symptoms varied, however, in each. In one there was remittent fever which fluctuated between nearly normal in the morning and 103° or 105° F. at night. The high temperature was followed by a chill and profuse sweating, after which it gradually fell to normal. The fever was accompanied by extreme emaciation and anaemia, and marked debility. In the other case the fever, identical in type with the first, never rose above 101.5° F., there was no anaemia, and the other symptoms were milder. The organism isolated was serologically like the bovine strain, and cattle inoculated with the culture aborted typically. As infection from pigs and goats could be ruled out, it was probable that the infection came either from the culture or from the milk. Recently Cayrel[3] has reviewed the question of the unity or the duality of these two diseases, and has drawn attention to the presence in Northern Italy of a prolonged fever in man which is definitely traced to infection through contact with aborted cows, and he claims that there is a very real danger of infection from cattle and from pigs, although he cannot say yet that this is identical with the undulant fever of goats. Theobald Smith has recently shown that the bacillus found in pigs more closely resembles the common human organism than does the strain commonly found in cattle. Izar,[4] however, finds that if a strain is grown on glucose agar and on normal agar the cultures from these two sources differ both morphologically and serologically. The culture from the glucose agar becomes coccoid and more readily agglutinable; while that on the ordinary agar retains its original characteristics. This may help to explain some of the conflicting results obtained by different workers. Nevertheless, it is certain that some strains of *Bacillus abortus* ingested in milk can produce a fever in man, but further work is necessary before we know accurately and definitely the relationship existing between Bang's bacillus and some as yet imperfectly described fevers in man. Meanwhile Wilson and Nutt[5] have found that about 5.7 per cent. of single milks in the Midlands are infected with the *Bacillus abortus*; elsewhere an incidence as high as 13 per cent. has been reported. Although human infection is possible with this organism, comparatively few cases have been described. This may be due to the fact that they have not yet been recognized as such, but it has been suggested that there may be another reason. The abortion organism is rare in the udders of cows in full milk, and when it does occur comparatively few bacilli are found—under 500 per cubic centimetre. On the other hand, when the milk is drying up, millions per cubic centimetre may be present, as in the normal milk from infected goats; in this state the milk is dangerous, and the infection, even in mixed milk, is gross. Whether this explains the epidemiology or not, there is little doubt that the question is one which merits the serious attention of bacteriologists and clinicians in this country.

TUT-ANKH-AMEN'S COSMETIC.

THE contents of a calcite jar found in the tomb of Tut-ankh-Amen by Mr. Howard Carter has been submitted to chemical examination by A. C. Chapman and H. J. Plenderleith of the British Museum Laboratory, the results of which are contained in a paper printed in the *Journal of the Chemical Society*. The jar contained a substance described as a cosmetic, but it is not stated whether it was for the skin or the hair. The results present many features of interest, not the least engaging of which is the unique view presented of the extent to which spontaneous decomposition may take place in a substance of a fatty nature during 3,300 years. The tomb, having been long

buried under a depth of ground and closely sealed, would provide a sterile environment, and it was noted that no bacteria were recognizable. The lid of the jar was cemented by a protective crystalline incrustation, an effect resulting from the action of moisture and saline matters contained in the dust of the local atmosphere. The contents of the jar weighed about 450 grams, or nearly a pound avoirdupois. It is described as rather sticky, and presenting the appearance of a heterogeneous mixture consisting of yellow nodules together with a chocolate-coloured substance. It became softened by the heat of the hand, and possessed a faint but distinctive odour which has been variously described as that of coco-nut or the flowers of broom, but rather valerianaceous. While the odour was decidedly fatty, there was no suggestion of rancidity. No vegetable structure or fibre could be distinguished by microscopic examination. Petrie and Quibell are quoted as having examined a fat found in Egyptian jars dating from an earlier period, in which they noted the presence of vegetable fibre, and suggested that its presence indicated that they were dealing with a fat obtained from a vegetable source. Chapman and Plenderleith, however, point out that the conclusion was hardly justified, for there is good authority to believe that the Egyptians had used a material composed of vegetable fibre as a wrapper for such articles. They also discount the suggestion that the coco-nut odour indicates a vegetable origin, for such a smell is frequently noticed in recently excavated specimens, and may be due to the ageing of resins or balsams used within the tombs. The chemical examination of the fat revealed, as was to be expected, only slender threads from which the original ingredients of the preparation might be inferred. Such direct evidence as would be obtainable from the finding of cholesterol, the invariable companion of animal fats, or phytosterol, the invariable companion of vegetable fats, was wholly wanting; whichever of these substances was originally present had wholly disappeared. It could hardly have been expected that either of them would survive the time. Indeed, it seems strange that the fats themselves had not wholly lost their fatty nature. This, however, they had preserved, but not without considerable modification of chemical structure. So far as could be judged from the chemical evidence, the fats had undergone hydrolytic cleavage into glycerol and free fatty acids; the glycerol remained largely unchanged, but the free fatty acids had combined with each other to form acid anhydrides, and those which were oxidizable had suffered oxidation—that is to say, such acids as oleic acid had acquired two or more hydroxyl groups. The investigations record the presence of 4.8 per cent. of free and combined glycerol, which the authors state is largely, if not entirely, in the free condition; but we do not see how to reconcile this proportion of free glycerol with the diminutive quantities of matters set down as soluble both in alcohol and water in the general proximate analysis. Nothing of the nature of wax was found. Since the waxes are generally more stable than fats, this observation seems definitely to decide their absence. The fatty acids actually recognized were stearic, palmitic, and myristic acids, and smaller amounts of acids more nearly related to lauric or capric acid. The chemical evidence generally would seem to exclude coco-nut and palm-kernel oils, and it does not seem probable that any vegetable fat would have been available having the small proportion of olein computed to have been originally present. From these data Chapman and Plenderleith conclude that it is highly probable that the cosmetic was composed of about 90 per cent. of an animal fat and about 10 per cent. of a resin or balsam. We note, however, that there is nothing contradictory to the supposition that it was composed of a number of fats of various kinds, such as may have been chosen for their rarity and high cost.

SOCIETY OF BRITISH NEUROLOGICAL SURGEONS.

A NEW society has just been formed—the Society of British Neurological Surgeons—with Sir Charles Ballance as its president. It has been felt that means by which workers in this most difficult branch of surgery could exchange experiences ought to be devised, and the present society is the result. Its membership is limited, and the quota of original members is necessarily very small. Provision has been made, however, for associates, who will be young surgeons showing more than ordinary interest in this branch of work. The society hopes to do useful work through this channel in helping men of this type in their earlier years to a wider knowledge than would otherwise be theirs. Visits to foreign clinics are to be a regular feature of the programme, and the smallness of the society's numbers should be a great advantage in this respect. The society will meet twice a year. Britain has a great heritage in neurology, not only on the clinical and more philosophical sides, but on the executive as well. The founders of the new society hope that it will play a worthy part, not only by reverence to the great dead and to tradition, but by a lively activity in the present. The inauguration took place at the Athenaeum Club on Thursday, December 2nd, 1926, with Sir Charles Ballance in the chair. Sir David Ferrier, Sir Edward Sharpey-Schafer, Sir Arthur Keith, and Professor Elliot Smith were present. These are emeritus honorary members, the fifth—Sir Charles Sherrington—was unavoidably detained in Oxford. The members of the committee are Mr. Percy Sargent and Mr. Wilfred Trotter, the honorary treasurer Mr. L. Bromley, and the honorary secretary Mr. Geoffrey Jefferson of Manchester.

TRISTAN DA CUNHA AGAIN.

WE recently (August 28th, p. 399) published a report by Dr. Marshall, the surgeon of the *Discovery*, of a visit made by that ship to the island of Tristan da Cunha, which was transmitted to us for publication by the Medical Research Council with the concurrence of the Secretary of State for the Colonies. The investigation into the dental condition of the inhabitants of the island and the relation of this to the peculiar circumstances of their diet and manner of life was made at the suggestion of the Dental Committee of the Medical Research Council. The visit was paid at the end of January, 1926, and only lasted two days, but Dr. Marshall made the most of his opportunities. Just a year before this visit the Rev. Henry Martyn Rogers and his wife quitted the island at the end of a stay of three years, the record of which, written by his widow, is now before us, and may be profitably compared with the record of the hurried visit of a year later. In *The Lonely Island*[1] Mrs. Rose Annie Rogers gives us the results of her prolonged study of the islanders at very close quarters. Other clergymen had lived on the island before Mr. Rogers and his wife arranged to spend three years there under the Society for the Propagation of the Gospel—the Rev. W. F. Taylor from 1851 to 1857, the Rev. E. H. Dodgson (a brother of Lewis Carroll) from 1880 to 1884 and again from 1886 to 1889, and the Rev. J. G. Barrow and his wife from 1906 to 1909. There Mrs. Rogers spent her twenty-first birthday, and there her son was born with no better help than that of an old woman of the island aged 87, of whom her patient writes: "Her sight is now beginning to fail, and she is obliged to have an assistant, but she is wonderful in many ways." Luckily Nature was kind, and the labour was presumably normal, but the risk bravely and deliberately run by this young wife was considerable. Mrs. Rogers draws a pleasing picture of the islanders; she describes them as affectionate, well behaved, honest, and

[1] *The Lonely Island*. By Rose Annie Rogers. London: G. Allen and Unwin, Ltd. 1926. (Post 8vo, pp. 223; 24 plates, 1 map. 7s. 6d. net.)

industrious. Many of the circumstances of this isolated community recall those of St. Kilda, which have been more than once the subject of comment in our pages.[2] For example, the fulmar petrel, or mollymawk, which plays such an important part in the life of the inhabitants of St. Kilda, is also of great importance on Tristan da Cunha, and the inhabitants of the one island are as subject to "boat-cough" as those on the other. The economics of the islanders were discussed sufficiently in our former article, and little need be added on this branch of the subject, save to note that there should not be much risk of actual starvation in a community which has at its command an inexhaustible supply of fish to be had for the catching, besides myriads of sea-birds and their eggs. The lack of vegetables and cereals is the most felt, but there is no record of the incidence of scurvy. To the student of sociology these descendants of European mariners and coloured women offer a most interesting study. There are some 135 people of all ages up to 90, living together without crime and without any written and hardly any unwritten law. They are by no means socialists, but by a kind of instinct the interests of the community seem to be protected. They have no currency. Force of character has its effect here as elsewhere, but however dominant a personality may be it does not confer recognized authority. This anarchism, as it might be called, is shown on the rare occasions of the visit of a vessel, when her commander may find a difficulty in making arrangements for the landing of stores owing to the islanders' tendency all to speak at once. Mr. D. M. Gane, the honorary secretary of the Tristan da Cunha Fund, who has himself visited the island, contributed to the *Solicitors' Journal* of October 18th, 1924, an interesting article on custom in Tristan, which Mrs. Rogers has printed as an appendix to this book. She has given a simple but moving story of her experiences, and drawn a pleasing picture of these poor but, generally speaking, happy people. That the island has its attractions is shown, not only by the indisposition of its own people to leave it, but by the fact that Mrs. Rogers's son, aged 15 months, "howled" on leaving, and wanted to go back there from Durban.

MEDICAL SOCIETY OF LONDON.

THE syllabus for the second half of its 154th session indicates that the Medical Society of London is as young in spirit as it is old in years. The subjects set down for debate are all of practical importance, and those invited to open them may be depended on to keep recent work in the foreground. At the first meeting on Monday, January 16th, Sir Humphry Rolleston will give his presidential address on "Changes in the clinical aspects of disease." The next meeting, on January 24th, will be a pathological evening. On February 7th a discussion on poliomyelitis will be introduced by a neurologist, Dr. F. M. R. Walshe, and a bacteriologist, Dr. Mervyn H. Gordon, who will be followed by a general physician, Sir Thomas Horder. On February 28th a discussion on acute abdominal emergencies complicating pregnancy and the puerperium will be opened by Dr. J. S. Fairbairn from the point of view of the obstetrician, and the surgical aspect was to have been introduced by his colleague Mr. Joseph E. Adams, whose untimely death we have to record elsewhere this week. On March 14th Dr. Jacques Forestier will give a demonstration on lipiodol injections, and on March 28th a discussion on a subject not yet announced will be opened by Sir Frederick Gowland Hopkins. Mr. Donald Armour's three Lettsomian Lectures on "The surgery of the spinal cord and membranes" will be delivered at 9 p.m. on February 21st, March 9th, and March 21st; the ordinary meetings all begin at 8.30 o'clock. At the annual general meeting on June 13th Professor Harvey Cushing will deliver the annual oration, and a conversazione will follow.

[2] Saint Kilda. BRITISH MEDICAL JOURNAL, July 10th, 1926, p. 80.

THE CENTENARY OF LAENNEC.

THE ceremonies celebrating the centenary of Laennec supplied a full programme on December 13th, 14th, and 15th, 1926. Those who have attended similar functions in Paris need not be reminded that "they order these things better in France." The official recognition of such a purely professional event is shown by the personal share taken in it by the Government. The President of the Republic attended, in state, the inaugural ceremony at the Sorbonne. On no fewer than three different occasions a Cabinet Minister not only presided but gave an address; and the city of Paris and its Prefect gave an official reception. The smoothness as well as the éclat of the various gatherings was remarkable, and reflects much credit on the organizing committee. If one might single out individuals, it should be mentioned that Professor Achard, the secretary of the Académie de Médecine, was the chief inspirer of the celebration, that Professor Chauffard was the wise and courteous president, and that the efficient secretary-general was Professor Roussy. We have already published the programme of the three days' meeting. There were a remarkable number of delegates from foreign countries, extending from Soviet Russia to Uruguay, and including representatives of the United States and Canada. At the official banquet there were spokesmen from no fewer than twenty-one separate nations to propose the toast of the memory of Laennec. It was well, therefore, that this country was fully represented. Sir John Broadbent represented the Royal College of Physicians of London, Sir Percival Hartley was the delegate of King Edward VII Sanatorium, Professor Edwin Bramwell came from Edinburgh, and Sir StClair Thomson was the official representative of H.M. Government and of the Royal Society of Medicine.

Auscultation in 1816; Laennec at the Necker Hospital, Paris.

SUBSCRIPTIONS FOR 1927.

MEMBERS of the British Medical Association are reminded that subscriptions fall due on January 1st, and that if each member who receives an application from the Head Office will send the amount to the Financial Secretary within the first week of the New Year the work of the office will be much lightened. Members are also reminded of the claims of charity, to which reference is made elsewhere. The amounts at the disposal of those who administer medical benevolence are altogether insufficient to meet the appeals that are received, and the British Medical Association Charities Fund was formed in order to assist. Every member of the Association is asked to add to his next payment a sum for the credit of this Fund.

WE much regret to announce the death, on December 23rd, 1926, of Dr. T. S. P. Strangeways, Huddersfield lecturer in special pathology in the University of Cambridge, and director of the Cambridge Research Hospital. We hope to publish an obituary notice next week.

Nova et Vetera.

FIFTY YEARS IN A MOORLAND PRACTICE.

To the annual meeting of the Yorkshire Branch of the British Medical Association Dr. Arthur C. J. Wilson of Penistone related his reminiscences of fifty years of country practice. Penistone is a market town, with steel works and sawmills, and stone quarries and collieries in the neighbourhood. It is on the edge of the moors between Manchester and Sheffield, which rise to an elevation of 1,200 to 1,300 feet. The town of Penistone is at an elevation of 760 feet, and Dr. Wilson said that his house is 800 feet above sea-level.

Dr. Wilson took his first diploma, that of M.R.C.S.Eng., in 1875, but before that he had done some work as a locumtenent, as was then allowed, and before going to Penistone had been accident house-surgeon to the Manchester Royal Infirmary. He started in practice in Penistone on February 14th, 1876. The following contains the chief passages in Dr. Wilson's address.

Country practice was very different in those days from what it is now, when you can get quickly over the ground in a motor car. The work then had to be done with a horse and trap or on horseback—I did all my night work on horseback. In summer it was pleasant enough in fine weather, but it was different in winter when we had the snow to contend with. There were no snow ploughs then. Penistone is a great place for snow. I had a thoroughbred mare, and as in winter many of the lanes were blocked with snowdrifts I used to get through the drifts by charging them at a gallop several times till I had made a way through. I have had a few accidents but never been seriously hurt. I have been thrown off my horse fourteen times and out of my trap ten times. The deepest snow I ever remember was in 1881. It was a beautiful morning at the end of November, but snow began about noon, and by 2 o'clock the roads were getting blocked. I had to go to Manchester, and my wife and I started back at 10 o'clock; we got to Penistone at 10 o'clock next morning, being all night in the train, and a wretched night it was. When I got home I started off on horseback to see patients. Except in Penistone, where paths had been cut, nobody had been on the roads. I rode three miles and then turned up a lane where I had three farms to call at. The lane was full of snow level with the top of the walls. With great difficulty I got to the first two farms, but when I tried to get to the next the snow was so deep that the horse could not get through it. I got off and tried to lead him, but he put his head in the snow quite exhausted. I managed to walk through the snow to the farm, and the farmer helped me to get the horse back. There were some patients I could not get to see for over a week owing to the depth of the snow. There have been many deep snows since, but never one that could compare with this.

Midwifery.

A good deal of a doctor's time in country practice used to be taken up with midwifery. There were very few midwives, and often all the assistance to be had was from some woman who had seen a case or two; consequently the patient could not be left till the child was born and for some time afterwards. I soon began to give the patients chloroform, and I gave it so often that it was a common saying, "Send for Dr. Wilson and his chloroform." I always kept the patient well under chloroform till the placenta had come away and I had got the uterus well contracted. Contrary to what might have been expected, I rarely had any haemorrhage. At first I always gave a hot vaginal douche of potassium permanganate, but for many years I have always given an intrauterine douche of mercury biniodide after all instrumental cases.

In 1905 I published a short article in the BRITISH MEDICAL JOURNAL on the treatment of puerperal eclampsia. To case I was called at midnight. The patient had become insensible, and was strongly convulsed. small bottle of chloroform with me, and I imme- put her under. The only person in the house was the husband, and I sent him for a midwife who lived a short distance away. When she came I went for my midwifery bag. The os was slightly dilated and I introduced Barnes's dilating bags, put on the forceps, and delivered a living child. The patient had no bad symptoms afterwards. She slept till midday, and wakened up feeling quite well. There was a good quantity of albumin in the urine, but it gradually disappeared. The second case I was called to at 2 in the morning. The father, who came for me, said that his daughter, who was unmarried, had suddenly gone into a fit. She had had dropsy, for which she had been attending a quack water doctor. When I got to the house I found the patient quite insensible; her legs were swollen, and she was pregnant—of which the parents had no knowledge. On making a vaginal examination, I found that labour had commenced and the os was dilating. I put her under chloroform, and used the forceps and delivered her of a living child. When she came out of the chloroform she was quite sensible. She had no bad symptoms afterwards, and the albumin disappeared from the urine. I attended four or five cases subsequently where I delayed giving chloroform, but I always found that the longer delivery was delayed the less good were the results. This treatment is entirely out of date and would be strongly condemned to-day, but at that time chloroform was looked upon as the best remedy for all cases of uraemic convulsions, and morphine was thought to be extremely dangerous.

I was called to a midwifery case one night, and found the os nearly fully dilated, with strong labour pains, but no progress was being made. I decided to apply forceps, and put the patient under chloroform, but the forceps would not pass. I passed my fingers further through the os, and found the uterus tightly constricted round the child's neck. It was a case of Bandl's ring; I gave more chloroform till I got the ring dilated, and then delivered. There were no bad symptoms afterwards.

Another case I was called to was a primipara, and although she had pains I could not make out any presentation. My son also examined her, and could not make out any presentation; he gave her chloroform, and I found the upper part of the vagina terminating in a cul-de-sac, but I managed to find a small opening, which I gradually dilated. The os was almost fully dilated, and I brought down a leg and turned the child. When the child was partly delivered the gas went out; the bed had been brought down into the kitchen, and it was a penny-in-the-slot meter. The woman helping us was a stranger in the house and did not know where the meter was. My son struck a match and found the meter, but could not find the slot, so we had to send for the husband. He came, and we got a light; all the time the child was partially born. The mother had septic mischief afterwards, but made a good recovery. She was going to live at Huddersfield, so I told her if she became pregnant again to go to the hospital and have Caesarean section. Over a year afterwards I was rung up one night from the Huddersfield Infirmary to ask what I had found when I attended this patient previously, as she had come into the infirmary in labour and no presentation could be found. Caesarean section was performed, but she died afterwards.

Another case I had in difficult circumstances was a primipara with a contracted pelvis, who lived in a caravan. I told her mother before labour commenced that she should be sent to the workhouse hospital, but she refused to let her go. It was a difficult forceps case; the patient was in a kind of berth, and I had to stand on a stool to give her chloroform and use the forceps. A nurse was there, but the caravan was so small that only one of us could get near the patient at the same time. I have also had four at a birth and three at a birth. All these cases except one I managed by myself, as it was often impossible to get any assistance except by waiting a long time.

I am surprised there were not more septic cases among my patients, as it was impossible to take aseptic precautions. When I first started in practice it was quite common for a woman to be confined with all her clothes on, and she was horrified if you asked her to get undressed; she thought it indecent. I induced all the patients to whom I gave chloroform to undress, and gradually got all the others to do the same.

Operations.

Besides midwifery I have done a good many operations. Patients whom I advised to have operations often said they would be operated on if it could be done at home. There were not the conveniences for conveying patients to the hospitals fifty years ago that there are to-day. I have amputated two thighs, two arms just below the shoulder, two or three legs, and several forearms. I have removed many breasts and tumours, and operated upon several empyemas with removal of a piece of rib. I have operated also for fistula and for strangulated hernia. The operations were nearly all done on the bed, as at small cottages there was no room to improvise an operation table.

The operations for strangulated hernia were all successful after the first two, to which I was not called early enough. Afterwards I always operated at once if I could not reduce the hernia under chloroform. One night I was called to a one-storied cottage with one room and a scullery. The patient was the man of the house, and the hernia had come down when he was at market. My assistant gave chloroform, and as I could not reduce the bowel I operated. It was a large inguinal hernia, and when I opened the sac several coils of intestine protruded. I divided the stricture but could not reduce the intestine. I pulled a little more down, and found a piece that looked almost gangrenous. At first I was undecided what to do with it, as the rule was then not to return any suspicious gangrenous intestine into the abdomen, but to leave it in the sac. However, I decided to return it into the abdomen and I ligatured the sac. The only light was from a candle held by an old woman, so the operation was rather difficult. The man made a good recovery without a bad symptom, and the hernia never troubled him again. I once operated on an old lady who had two large femoral hernias; one of them had been strangulated for two days. I told her husband that I was doubtful about the result of operation; but she made an excellent recovery, and complained only that I had not operated on the other side at the same time.

Operations were often done under great difficulties. One, of amputation below the shoulder-joint, was done in a small one-roomed cottage with a window two feet square. I had to do it by candle-light. The wound healed well.

Forty years ago I removed, from a woman aged 40, a tumour of the breast which I was certain from its appearance was a scirrhus, but there were no enlarged glands in the axilla. A month later she came with an enlarged gland in the axilla, which I removed. A fortnight ago I was in a house, and there was an old woman of 80 years who had walked two miles and was walking home again. This was the woman I had operated upon forty years before.

Inquests.

I have had to make a good many *post-mortem* examinations—two in murder cases on women who had been shot. Another was on the body of a man who had been drowned in the river and had not been found for some time and was much decomposed. I made another *post-mortem* examination on the body of a little child about a year old. It had died suddenly in the night, and the mother said it had not been ill. I found a perforated appendix with an abscess round it. In yet another instance I was called by the police to the body of a man who had been found dead by the side of the road; his bicycle was near him, and he had evidently been thrown off and fractured the base of his skull. Nothing was found by which he could be identified, but in a small case in which he had packed some clothes was a sheet of paper on which was a rough draft agenda for a meeting of a Branch of the British Medical Association, but it did not say where it was to be held. One item on it was, "Dr. Kitchen will move a resolution." Now we did not know where the man had come from, but I remembered a fellow student named Kitchen, who afterwards started practice in Cheetham Hill, Manchester. I knew he was dead, but on looking in the *Medical Directory* I found there a Kitchen, evidently his son, practising in Cheetham Hill. The inspector of police communicated with the Manchester police, who ascertained from Dr. Kitchen that the dead man was evidently a young doctor from Whalley Range, the secretary of the Branch. He had been riding from Manchester to Barnsley to stay the week-end with some friends.

Railway Accidents.

In June, 1884, a serious accident happened to the London express from Manchester, which, owing to the crank axle of the engine breaking, ran off the lines and rolled down the embankment at Bullhouse Colliery, two miles from Penistone. I was district surgeon to the railway company, and went to the scene in a special train the station-master had got ready. Luckily I had given ambulance lectures during the previous winter, and several of the ambulance men went to the accident. Dr. Watson, another Penistone doctor, and my assistant also went there. Twenty-four passengers were killed. The most serious cases, numbering thirty, were carried up the embankment by the ambulance men and put into railway carriages. I went with these serious cases to Manchester and got them conveyed on ambulance stretchers to the Manchester Infirmary. I was thanked afterwards by the directors of the railway company for what I had done. Another accident occurred in April, 1885, at 1 a.m., to a special train running from Liverpool to the Oxford and Cambridge boat race. I was the only doctor there, as my assistant had just been called out. One man was killed and about ten seriously injured; they were conveyed to the hotel near the station.

In the Bullhouse railway accident a lady who lived at South Kensington sustained a compound fracture of the leg; she was removed into a small house near the accident, and I attended to the fracture. Her husband asked me when his wife could be removed to London, and I told him I would put the leg in a plaster bandage in a fortnight, and then she could be removed. I had had a good deal of practice in setting fractures, both simple and compound, and putting on plaster bandages, both at the infirmary and after I began practising. Before I went to Penistone a plaster bandage had not been heard of. I put one on to the first case of fractured leg I treated, and when the people saw a man walking about on crutches with a fractured leg it quite surprised them, and I was always called to fractures afterwards for miles round Penistone. Two days later the lady's husband asked if it would be safe to remove her so soon, as his brother in London had mentioned it to his physician, who said it was most dangerous and he did not believe in plaster bandages. The next day I went to see the lady; I took Billroth's *Surgery* with me, and showed the husband what it said about moving cases with plaster bandages on. He made a note of the name of the book, and two days later when I called he had got another letter from his brother, in which his physician said he had not had much experience with plaster bandages, but they had better be guided by the doctor who was attending the case, as he evidently knew what he was doing. I put a plaster bandage on with a trap-door to dress the wound, and she was removed in a saloon carriage to London in a fortnight. I saw her when I was in London a week afterwards, and about a year later she sent me word that she could walk quite well and it was difficult to tell where the leg had been broken.

Epidemics.

Though during my fifty years I have had some periods of very hard work, especially during epidemics of influenza, small-pox, typhoid fever, scarlet fever, and diphtheria before antitoxin, the worst time I had was in 1917 and 1918, when my son wished to go to the war and was sent to Egypt. As my experience with locumtenents was not fortunate I decided to do the work myself. It was very hard, but I managed pretty well till the influenza epidemic of October and November, 1918, which was very bad for a month. In seventeen days I visited 833 houses (an average of 49 a day), and I saw 1,219 patients in the houses (an average of 71 a day). One day I visited fifty-six houses and saw 126 patients. I had six instrumental confinements with chloroform during the same period, and one *post-mortem* examination and inquest. I had over thirty miles a day to go to see these patients. I had besides three surgeries a day—one of my son's and two of my own—which were always crowded.

Besides practice I have done a little scientific work. I fitted up a laboratory in one of my cellars and did water and milk analysis, as I was medical officer of health for three districts. Afterwards I did some bacteriology and cultivated the diphtheria bacilli from throats and examined the sputum for tubercle bacilli, as there was no West Riding Laboratory then to which specimens could be sent free.

Public Work.

I have also done some public work. When I had been in Penistone a year a deputation from a ratepayers' association asked me to stand for the local board; I agreed, and was elected at the top of the poll. Next April I shall have been on the local board—now the urban district council—fifty years. I have taken a very active part in obtaining a water supply, a market, council offices, a public hall, and free library. I am vice-chairman of the council and chairman of the Waterworks and Sanitary Committees. For three years I sat on the board of guardians. For nine years I was a member of the West Riding County Council. I was made a county magistrate in 1903, and for a time attended the Barnsley court every week. I have taken an interest in education, and for a number of years have been chairman of the governors of Penistone Grammar School and chairman of the local Elementary Education Committee.

MEDICAL INSURANCE AGENCY.

A MEETING of the Committee of Management of the Medical Insurance Agency was held in the House of the British Medical Association on December 8th, 1926, when Sir Humphry Rolleston was in the chair. A discussion took place with regard to the way in which the Agency could best give assistance to the Council of Epsom College, but no final decision was reached. Meanwhile, it was resolved to place a sum of £100 at the disposal of the headmaster of Epsom for the purpose of assisting to defray the cost of education of certain deserving boys already at the College who would otherwise have had to leave owing to failure of family resources, due to the death or disablement of parents.

An interim report for the nine months ending September 30th, 1926, was presented. It showed that the Agency had not only maintained the high standard of former years, but had made further progress in all branches of its business, except workmen's compensation insurance. This class of insurance is expected to diminish, as it is not now the practice to effect workmen's compensation insurance in respect of servants under separate policies, as these risks are included in the "Comprehensive" household contracts recommended by the Agency.

The life assurance policies completed through the Agency numbered 162, representing in sums assured the large amount of £148,176. In 1925 the number of proposals was 138, and the sum assured £134,394. Many life policies have been negotiated this year on behalf of members resident in India, China, the West Indies, Mesopotamia, and Egypt; inquiries have also been received from South Africa. It has hitherto been the practice of most life companies to charge an extra premium to members of the Naval, Military, and Air Force; one of the principal companies with which the Agency does business has, however, this year decided to abolish such extra premiums, except in special circumstances. Steps will be taken to communicate this decision—the effect of which will be felt later on—to members, especially those serving abroad.

In motor car insurance the rates of premium charged under the doctors' special policy are moderate, and compare favourably with those of tariff companies with which the Agency had previously placed business. Nevertheless, the premium income has increased by over £1,000 in the period under review. The rate of loss on renewals of previous insurances is extremely low and is more than counterbalanced by the number of new entrants, which totals 174, making with old clients a grand total of 1,074 separate policies, many of which include two and even three cars. The underwriters employed have rendered good service, and disputes in regard to settlements of claims have been rare. In cases where disputes have arisen the has been able to effect satisfactory and equitable settlements. The underwriters have had to meet some heavy claims since the beginning of the year, and although it was thought that it might be possible to secure even better terms in the coming year, experience, unfortunately, does not at the present time warrant the Agency in approaching the underwriters in this sense. One claim alone, amounting to over £2,000, had to be met, and claims of £200 to £300 have been paid, nominal sums sufficing in other cases. The arrangement by which Messrs. Mann, Egerton and Co. act as consulting motor engineers has proved satisfactory, and is being continued. One or two minor disputes have unfortunately occurred, but the evidence goes overwhelmingly to prove that this service is appreciated.

Conversations have been held with the officers of an insurance company with a view to devising a satisfactory scheme for the advancement of money to medical men and women for the purchase of partnerships or practices; a full detailed statement cannot yet be made, but the outline is roughly as follows: The company is prepared in principle to advance sums up to two-thirds of the purchase price without personal guarantee, charging instead their funds under a fidelity policy. Interest rates have been reduced from 7 to 5½ per cent., and the term for repayment has been extended in approved cases from four to six, seven, or even ten years. A method of dealing with applicants by means of a small committee consisting of a representative of the insurance company, a medical agent, and the Financial Secretary of the British Medical Association, has been discussed. Loans will be secured by a life policy equal to 150 per cent. of the sum advanced and an adequate sickness and accident policy.

The following grants were made to the medical charities in respect of the year 1926:

	£	s.	d.
Royal Medical Benevolent Fund	525	0	0
,, Christmas Appeal	105	0	0
Royal Medical Benevolent Fund Guild ...	525	0	0
Royal Medical Foundation of Epsom College...	210	0	0
Headmaster, Epsom College	100	0	0
M.I.A. Girls' Education Subcommittee ...	210	0	0
B.M.A. Charities Committee (to be paid in 1927)	157	10	0
Royal Home for Incurables, Putney	52	10	0
Royal Medical Benevolent Fund of Ireland ...	26	5	0
	£1,911	5	0

CHILD LIFE INVESTIGATIONS.

Dead Births and Neo-natal Deaths.

THE report of the Medical Research Council on the recent investigations at several centres throughout Great Britain into the causes of dead birth and neo-natal death has just been issued. It offers a clinical and pathological study of 1,673 cases of dead birth and neo-natal death, the chief contributions being due to Dr. F. J. Browne, Edinburgh (400); Drs. Cruickshank and Kennedy, Glasgow (400); Drs. Palmer, Phillips, and Taylor, London (369); Drs. Capon and Wilson, Liverpool (354); and Dr. Strachan, Cardiff (150), while additional data were obtained from Miss E. E. Hewer in the London School of Medicine for Women. It had been arranged that the reports of all these observers should be collected and edited by Dr. J. W. Ballantyne of Edinburgh, and at the time of his unexpected death in January, 1923, they were in his hands for this purpose. The work was afterwards undertaken by Dr. Eardley Holland, who obtained the collaboration of Dr. Janet Lane-Claypon, working direct for the Medical Research Council.

As might be expected with several observers working independently and without any previously arranged plan for a uniform classification of their results, it was found that there were various discrepancies and disparities in the reports from the several centres, and the compilers therefore considered it necessary not merely to collate and edit the reports but to write their own report on the basis of the evidence supplied. The result is a pamphlet of some 90 pages containing a digest and summary of the various reports. Its small bulk will probably be disappointing to some who were acquainted with the vast amount of detailed matter that had been submitted from the centres, but it should be remembered that much of the

work had been already published, though generally in an abridged form, either in the Special Report Series of the Medical Research Council or in articles in medical journals. A list of the chief contributions already published in this way is given in the present report.

One of the main sources of difficulty in co-ordinating the results lay in the fact that some workers had classified the causes of foetal and neo-natal death according to *post-mortem* findings, as, for example, cerebral haemorrhage and asphyxia, subsequently working out in detail the clinical cause, such as contracted pelvis, which had led to the pathological condition; while others had put in the forefront the clinical cause, the resulting pathological condition being regarded as a "consequent factor." The compilers have in their report used a clinical etiological classification for all cases, arranging them under the following headings: complications of labour, ante-partum haemorrhage, toxaemia of pregnancy, syphilis, maternal diseases, placental states, foetal states (excluding syphilis), prematurity, and post-natal causes.

The reports showed unanimously that the most common causes of foetal death are "complications of labour," which furnished 35 per cent. of the total number. The most fatal complications were contracted pelvis and abnormal presentations, which accounted for 38 and 30 per cent. respectively of all the deaths from this cause, while difficult and prolonged labour unassociated with either contracted pelvis or abnormal presentations caused 12 per cent. and normal labour 5 per cent. of the total deaths due to complications of labour. This means that at least 85 per cent. of the deaths due to complications of labour should be preventable by adequate ante-natal supervision. Thus, 99 deaths out of a total of 465 were due to breech or transverse presentations that with adequate care should be almost entirely preventable. As regards the deaths due to contracted pelvis, it is pointed out that in many cases the mother had been forty-eight hours or more in labour before admission to hospital!

> "It is impossible to say to whom the delay was due, but inasmuch as the majority of women send for either the midwife or the doctor either at or shortly after the onset of labour it is hardly likely that the fault lay with the mother. In one instance it is recorded that the midwife kept the case in her own hands for two days and two nights before sending for the doctor."

Still, even with the most careful and expert ante-natal and obstetrical care, there will probably always remain a small proportion of cases in which foetal death is beyond our power to prevent—for example, those due to coiling of the cord round the neck or body, and, to a lesser extent, those due to prolapse of the cord or premature rupture of membranes. Thus coiling of the cord around the foetus was almost as frequent a cause of foetal deaths as persistent occipito-posterior positions, though it is probably true that diagnosis of the former as a cause of death was in the majority of cases arrived at by a process of exclusion, and in the absence of any other well defined cause of death.

Intracranial Injuries.

The reader will be surprised to find that neither under this heading nor anywhere else throughout the report is there any reference to cerebral haemorrhage. This is surely a regrettable omission. A review of the causes of foetal and neo-natal death without any reference to cerebral haemorrhage is like *Hamlet* without the Ghost. Throughout this section the term "intracranial lesion" is synonymous with tears of the dural septa. The main conclusions regarding them were as follows:

1. Tentorial tears occurred in half the cases of spontaneous breech delivery.
2. Interference with forceps causes the same proportion of tentorial tears.
3. Intracranial lesions (tentorial tears) were found in about one-third of all cases of version.
4. Taking all cases into consideration together tentorial tears were found in just over one-fourth of all cases.

Ante-partum Haemorrhage.

In this section are considered 122 foetal deaths from placenta praevia and 129 from accidental haemorrhage. Perusal of the tables brings to light at once the fact that, while in Glasgow 97 deaths out of 400 were due to ante-partum haemorrhage, in Edinburgh, where a similar number of cases was dealt with, only 37 were due to the same cause. This disparity might be due to the fact that in Glasgow a larger proportion of practitioners send their cases of ante-partum haemorrhage into hospital, or it might be due to the methods of treatment adopted, assuming, of course, that the cases were not in any way selected by the workers concerned; on these points no data are available. Notes of urine examinations were available in only 23 of the 122 cases of placenta praevia, and in 9 of these the urine was normal, while in 14 there was albumin in varying amounts. One woman had had oedema and swelling of the feet for seven weeks before delivery. It is apparent, however, that there is always room for considerable error in the diagnosis between placenta praevia and accidental haemorrhage. For instance, a case of external accidental haemorrhage, in which albuminuria is exceedingly likely to occur, may be easily labelled as a partial placenta praevia. In some cases, indeed, the diagnosis between these two conditions is probably impossible, and therefore, before any conclusion can be drawn regarding the significance of albuminuria in ante-partum haemorrhage, all doubtful cases should be rejected. Much of the disparity, for example, between the various published accounts of the frequency of albuminuria in accidental haemorrhage may be due to the fact that some cases diagnosed as accidental haemorrhage are in reality placenta praevia of minor degree. It is interesting also to note that between syphilis and ante-partum haemorrhage no relation was found to exist.

Syphilis.

The responsibility of syphilis in the causation of foetal death was found to be lower than would be generally expected, as it only accounted for 5.4 per cent. of the deaths in the entire series. Among macerated foetuses the percentage of syphilis is naturally greater, and works out at 26 per cent. Whitridge Williams gave figures that are much higher, 12.8 per cent. of foetal deaths among the white population in his clinic being due to syphilis, while he estimated that 80 per cent. of all macerated foetuses were syphilitic. There can be no doubt, however, that the above figures represent the highest incidence of syphilis among the maternity hospitals of this country, and, indeed, is probably even too high, as in certain of the centres (Edinburgh, for example) the maternity hospital has a venereal department in which cases of syphilis are treated and afterwards confined. Many cases come from a distance that would not find their way to the hospital at all if such a department did not exist. The Edinburgh cases are necessarily, therefore, in some degree selected, and do not represent a fair sample even of the hospital population. This is borne out by the Edinburgh figures, which show a high percentage of syphilis—7 per cent., as compared with 3.7 per cent. from Glasgow, 4.6 per cent. from London, and 5.6 per cent. from Liverpool, while Cardiff showed an incidence of 7.3 per cent.

The report concludes with a short review of the results obtained. These may be summed up in the need for ante-natal supervision, with consequent reduction of the necessity for obstetric intervention, by the early discovery of such conditions as pelvic contraction, by the routine examination of the urine, and by the provision of hospital accommodation with skilled obstetric care for such emergencies as have not been or cannot be prevented. In the words of the report:

> "Such a state of affairs can, however, hardly be expected until the teachers in the medical schools and the teachers of midwives, as also the leaders of the numerous women's organizations, are convinced of the need for and the scope of ante-natal supervision. . . . In many of these cases it is not merely a hospital bed that is required but skilled obstetric care. With improved supervision during pregnancy no doubt the number of emergency obstetric operations would decrease, but even so, skilled supervision would be required. It can hardly be doubted that much can be accomplished without additional cost if closer co-operation were established."

THE SPREAD OF INFECTION IN SCHOOLS AND SHIPS.

THERE is no more fascinating epidemiological problem than that of the spread of illness within a community either completely isolated from the rest of the world or receiving immigrants at different rates. In recent years this problem has been most closely studied by experimental workers. The English pioneer has been Professor W. W. C. Topley of Manchester, who has made it a principal object of his researches since 1919; in the last four or five years Professor Topley has been associated in the investigation with Dr. Major Greenwood of the Ministry of Health. The nature of this collaboration has been misunderstood. One of the psychological mysteries of our profession is that, although the general public consider the opinions of, say, an operating surgeon, a practising physician, and a bacteriologist of equal value upon any professional topic whatever, within the profession itself it seems to be an axiom that nobody practising a specialty has any knowledge of anything else. Drs. Topley and Greenwood have collaborated strictly, and the terms of their working agreement were: "That we should each bring into the common stock such special knowledge of particular techniques as we had individually acquired, but that the business of the firm should really be a joint one, that neither partner was at liberty to disclaim not mere formal but real responsibility for the work of the other."[1] These being the conditions of their partnership, their joint conclusions are: (1) That a community of mice can never be rid of an infectious disease once introduced, so long as non-immune immigrants continue to be admitted to the community. (2) That the rate of circulation of the non-immune entrants is an important factor of the epidemicity of the disease. As these authors put it: "We would sooner admit 1,000 susceptibles to a herd at once than 10 a day for a hundred days if we desired to keep down the rate of infectious disease."[2]

These were not the only, perhaps not even the most important, conclusions reached, but those most directly relevant to the extremely interesting memoir by Surgeon Commander Sheldon F. Dudley, R.N., which the Medical Research Council has just published.[3] The strong points of the Topley-Greenwood method are obvious—for example, large numbers of animals at risk and power to modify the external conditions. The weak points are equally obvious. The workers are dealing with animals who cannot be cross-examined and with infections of no great practical importance to human communities, while their criterion of infection is only applicable *post mortem*. Surgeon Commander Dudley, who is acquainted with Topley's earlier publications and has himself already published an important study of the epidemiology of diphtheria, examined the records of various schools and institutions, and now interprets them in a way which, as the Medical Research Council note in the preface, increases the probability that the Topley-Greenwood hypotheses are correct.

Part I of the report deals with the medical statistics of the R.N. School, Greenwich, from 1912 to 1924. Surgeon Commander Dudley notes that the course of influenzal morbidity affords an almost exact parallel with Topley's observation on mouse "typhoid" in the recrudescence of morbidity (taken as the human analogue of the mortality in mice) when fresh susceptibles are introduced. "During the epidemic the introduction of a batch of uninfected boys was followed first by morbidity among the freshly introduced material, and next by increased morbidity in those who had previously escaped infection, and reinfection of some of those who had been infected earlier in the epidemic." In treating of diphtheria, Surgeon Commander Dudley suggests that the ratio of Schick-negative to Schick-positive reactors may be taken as an "index of herd immunity," and relates the falling curve of herd immunity to the rising curve of clinical morbidity. The second part of the report deals with general principles and the relation of the carrier to the production of herd immunity. It is argued that there are—

"three variables: First, the amount of infective material received by the host per unit of time. Second, the rate at which this infective material can be destroyed. The third variable is the rate at which microbic proteins stimulate (or depress) the immunity mechanisms (specific or non-specific) of the host. . . . Other factors being equal, including time, it will depend on the distance of a susceptible host from a distributor of parasites as to whether the former becomes a case, or a carrier, or possibly immune to infection by merely destroying or absorbing the parasitic proteins. It should be noted that, though the theory termed the velocity of infection can completely explain the cessation of an epidemic which coincides with a diminution in the carrier rate, and in the density of the population, yet this hypothesis cannot by itself account for the cessation of an epidemic where the sleeping conditions remain unchanged, the carrier rate increases, and fresh susceptible material is frequently introduced, as was the case with the diphtheria epidemic in Greenwich Naval School. Under such circumstances another factor is required, which is probably bacterial variation in response to changes in the herd immunity. Thus carriers acting in a suitable environment may prevent large disease outbreaks by supplying subinfective doses of infectious material to the more susceptible members of a population. In this way the general resistance to epidemic disease is increased, and the herd is vaccinated by its carriers."

The author, of course, guards himself against the implication that he holds carrier infection to be the only or even the commonest mode of distribution of microbic disease. In subsequent pages data from the London Foundling Hospital, a warship, and two naval training establishments are examined, and the author finds them to be in conformity with his views. In the next section relative incidence is briefly examined, and after that the author takes up the study of the influence of the rate of change of the population upon the development of infectious illnesses. The author's algebraical treatment of this is, necessarily perhaps, rather too crude to be more than suggestive, but the following remarks are interesting.

"The recruits at Shotley were older and came from, if anything, a slightly poorer class than the Greenwich boys; the herd immunity at Shotley should therefore have been higher than at Greenwich. In spite of these facts the morbidity from infectious disease was practically as high at Shotley as at Greenwich. This paradox puzzled the writer until the obvious and simple fact dawned on him, that the population was changing at Shotley three times as rapidly as at Greenwich. The rate of change of population is of special interest to the Services, as it is probably the chief factor in the high incidence of disease in recruiting depots; it is doubtless of far more importance than unaccustomed conditions of living, or mental and physical strain."

There follows an examination of war-time statistics of epidemic meningitis, leading to the conclusion that "all naval experience goes to prove that the average age of a community, in so far as it indicates a greater or less herd immunity, is one of the most important factors in determining the incidence of cerebro-spinal meningitis." Lastly, there are two short sections on periodicity, and upon pneumonia and rheumatism. The former leads to the conclusion that the "differences in the morbidity of the various establishments which have been described are determined much more by the intrinsic characters of the establishment than by the density of disease in the surrounding area." The latter suggests, having regard to the experience of some naval institutions, that damp and chill are more important etiological factors of rheumatic disorders than overcrowding.

In a short summary such as this it is impossible to do justice to a detailed argument, still less to indicate difficulties of interpretation of complex facts. We do not doubt that some of Surgeon Commander Dudley's conclusions will be modified as our knowledge increases, and probably all epidemiologists will not accept all his explanations. We believe, however, that he has made an important contribution to epidemiological literature. The development of experimental epidemiology is one of the most hopeful features of the present epidemiological situation; its integration with field observations—as in Surgeon Commander Dudley's report—is an essential element of progress. In giving generous financial support to Professor Topley's experimental work, and in publishing such papers as that of Surgeon Commander Dudley, the Medical Research Council is once again performing a service of more than national importance.

[3] The Spread of Droplet Infection in Semi-isolated Communities. By Surgeon Commander Sheldon F. Dudley, R.N. Medical Research Council, Special Report Series, No. 111. London: H.M. Stationery Office. 1926. Price 1s. 6d.

Union of South Africa.

[FROM OUR CORRESPONDENT IN JOHANNESBURG.]

TWENTY-FIRST SOUTH AFRICAN MEDICAL CONGRESS.

THE twenty-first South African Medical Congress was held in Pretoria during the second week of October under the presidency of Dr. A. W. Sanders. It was a little early in spring for Pretoria to be seen at its very best, but already the flowering trees which line the wide streets were beginning to burst into masses of mauve, orange, and red flowers. A fortnight later members would have seen the wondrous sight of mauve carpets under the jacarandas where the fallen flowers lie thick like coloured shadows beneath the trees. Pretoria in its early spring drapery tended perhaps to produce a mood of poetry rather than of strenuous scientific endeavour; nevertheless, and in spite of the numerous social attractions provided by the people of Pretoria, important and earnest discussions took place on the many problems in medicine and hygiene which face us in South Africa, and much valuable work was done.

The invitation to the Congress had been issued by the Pretoria Branch of the British Medical Association and the South African Medical Association, now happily united into one body styled the "Medical Association of South Africa (British Medical Association)." At the opening ceremony in the extra-mural building of the Transvaal University College, Dr. A. J. Orenstein, President of the Federal Council of the Medical Association of South Africa, inducted Dr. Sanders into the presidential chair, and then Congress was formally opened by Advocate W. S. Duxbury, K.C., Mayor of Pretoria. In an eloquent address he bade the members of Congress welcome on behalf of the people of Pretoria, paid a high tribute to the achievements of medical science in South Africa, and expressed the confident expectation of the public that the many problems of human disease would be steadily attacked and conquered by the medical profession. Residents in Pretoria, he said, were brought into very intimate association with some of the problems with which the Medical Congress would deal. "Within our borders, and in addition to the clinics which discharge the valuable functions of preventing, as far as may be, and of repairing the ravages of specific and other diseases, and to the institutions more definitely devoted to the vital requirements of motherhood and child welfare, we touch, through our Mental Hospital and its 1,500 inmates, what perhaps is the most intricate side of your profession. Fascinating, too, though exceedingly trying to the layman, are the various manifestations of the leper's terrible physical inflictions, in their interrelationship with his mental make-up. These are matters which we are not allowed to forget, by reason of the existence of the leper institution at West Fort, a few miles away. Patient research into the etiology of the dread disease is at the present time being carried on at West Fort, and they too have had their Father Damien, who, in the person of a devoted medical man, sacrificed his life in the cause of scientific observation in the field."

THE PRESIDENTIAL ADDRESS.

Alfred William Sanders, M.D.Lond., F.R.C.S.Eng., was born in London in 1872, and, after a brilliant student career at St. Mary's Hospital, came to South Africa first in 1899 as civil surgeon with the Imperial Forces; in 1901 he was appointed district surgeon of Pretoria, and surgeon to the Pretoria Hospital. In 1908, when an honorary staff was appointed to the Pretoria Hospital, he became honorary surgeon, an appointment he still holds. Since 1913 he has been a member of the Transvaal Medical Council.

Dr. Sanders, in his presidential address, made reference to the sad circumstances that had brought him to occupy the chair. Dr. Howell-Davies, who had been unanimously elected President by his colleagues in Pretoria, had died after a short illness; he had richly deserved the honour done him, and was hard at work in making arrangements for the Congress when he was called away. So keenly had all felt this loss that the abandonment or postponement of the Congress was seriously discussed. It was, however, realized that to take such a step would have caused considerable inconvenience to many who had already made arrangements to attend, and would have gravely interfered with the very important business which had to be transacted at the Congress, more particularly the amalgamation of the British and South African Medical Associations. Dr. Sanders sketched the career of Dr. Davies in Pretoria. "Davies was a man of great public spirit. It was largely through his instrumentality that the Victoria Maternity Hospital was instituted, and he was always an active member of its board of management. Ever alive to the best interests of his profession, he keenly resented and attacked anything likely to lower its status or to bring it into disrepute. During the last few years of his life he was president of the Clinical Society, which he had practically brought into being, and which did much excellent work. His domestic life was a very happy one, and his family and a large army of patients must keenly mourn his loss."

The Medical Congress was a very important event, bringing together men from all parts of South Africa. There were present prominent members of the profession from the larger centres of population, where they had every known aid in the practising of medical science in the most favourable circumstances, and others who, living in the country districts with none of the medical amenities of town life, had to tackle difficult cases single-handed and to shoulder heavy responsibilities alone. The advantage of bringing such men together was evident.

The subject which he believed Dr. Davies had been preparing was "The coming generations," and he proposed to deal with it to the best of his ability. Every child had the right to be well born, and as knowledge of heredity increased it was being realized more and more that if good stock of any kind, animal or vegetable, were to be produced it must be from the best material only. The responsibilities of parenthood were lightly undertaken and lightly sanctioned, and an endeavour should be made to ascertain the causes of racial deterioration. The frankly and markedly defective were relatively easily dealt with, given the necessary power, either by segregation or sterilization, and there must be few who would contest the need for some such measures. It was necessary to insist on more and better scientific education in the schools. It was the right of every child to receive instruction in the facts of life. No boy or girl should leave school without a good working knowledge of biology and the collateral sciences, physiology, chemistry, and hygiene. The study of human heredity and evolution should begin in the schools, and when a child could be brought to understand how health and vigour in individuals was to be sought after and attained he would go far to realize the grandeur of the results to be achieved by the widespread or national utilization of such principles. The schoolmaster and the schoolmistress must be the comrades of the doctor. Syphilis and alcoholism were to be attacked by every available means. Every municipality should organize popular lectures, by medical men to men and by medical women to women, on the prevention of venereal disease. A real danger in South Africa was the association of possibly infected coloured nurses with white children. The greatest care was needed and should be exercised in that regard. Climate was an environmental factor which, while it could not be directly altered, much could be done and had been done to improve. The draining of swamps and the clearing away of rank vegetation had achieved wonders. Malaria was the environmental disease which most threatened the life and health of the white man in South Africa. Endemic in much of the coastal area and in large parts of Northern and Eastern Transvaal, it was responsible for many deaths and marked deterioration, both mental and physical, in the local population. Those who lived in Pretoria were in close touch with the peoples of both high and low veld, and had frequent opportunity of judging its effects. Bilharziasis was a disease which affected many children, often producing most serious consequences. Thanks to the method of treatment by intravenous injections of antimony potassium tartrate, comparatively recently introduced by Christopherson, this disease,

against which there had previously been practically no remedy, was now well within control. The working out of the life-history of the parasite by Leiper, work which had been repeated for local conditions by Dr. Anne Porter of Johannesburg and by Dr. Cawston of Durban, gave hope that much might be done to prevent the disease. The welfare of the coming generations should not be left to Nature and to evolution.

Sectional Meetings.

All the special subjects set down for discussion in the various sections of the Congress were earnestly discussed, and several of them were continued at adjourned meetings. Prognosis in heart disease, a subject introduced by Dr. Hugh Smith, in the Section of Medicine, proved to be of considerable interest to a very large proportion of members. In the Section of Surgery the special subject was surgery of the gall bladder, on which Dr. R. L. Daly read a paper, the discussion being opened by Dr. J. W. Brebner. The special subject in the Section of Public Health, the prevention of infantile diarrhoea, was discussed at great length, many country practitioners contributing their experiences. In the Section of Obstetrics and Gynaecology the special subject was the treatment of suppurative salpingitis; it was introduced by Dr. I. J. Schabort, and the discussion was opened by Dr. R. W. B. Gibson. Many of the other papers were well debated. These included: "Some sequelae of encephalitis lethargica," by Dr. M. J. Cohen; "Theory and practice of heliotherapy," by Dr. L. E. Hertslet; "Incidence of surgical diseases in the Bantu natives," by Mr. C. F. Beyers; "A South African carbohydrate used in infant feeding," by Dr. B. G. Melle; "Serological diagnosis of typhoid fever," by Drs. Pijper and Pullinger; "Dimensional differentiation of certain microbes," by Dr. A. Pijper; "Complement fixation for tuberculosis in South Africa," by Dr. B. D. Pullinger; "Pituitrin v. forceps," by Dr. Bruce Bays; "Team work in the diagnosis of cerebral tumour," by Dr. F. H. Kooy; and "Some results of trephining operations for glaucoma," by Dr. A. G. Brinton.

Social Side of the Congress.

The citizens of the capital had been at great pains to arrange suitable entertainment for members of the Congress and their wives, and their efforts were highly appreciated. There were social functions every afternoon and night, and it was quite impossible to do justice to them all. The ball was crowded, and in spite of the heat some members were observed doing the Charleston, which has invaded the Union. At the official banquet there was also a very large gathering. The guests included His Excellency the Governor-General and the Administrator of the Transvaal, the Hon. J. H. Hofmeyr. The toasts of "The King," "The Governor-General," and "South Africa" having been duly honoured, His Excellency replied. He congratulated the profession in South Africa on the wise decision to form a federation with the British Medical Association; the Medical Association of South Africa had his best wishes for its successful future. The fellowship between the members of the medical profession was one of the principal sources of its strength; new lines of treatment, new discoveries in all departments, were generously shared; there was no room for trade secrets, and the work of the leaders was accessible to the humblest member of the profession. Members of the public ought to look upon the doctor more as their adviser in the ways of maintaining health than as their attendant when ill. The importance of keeping well was not sufficiently stressed, and at least as much attention should be devoted to this as to curing their bodily ills.

The Administrator of the Transvaal proposed the toast of "The Medical Profession" in a witty speech. He joined with His Excellency in congratulating it on the greater unity achieved in South Africa. The problem was one of combining autonomy with membership in a larger body; of maintaining and safeguarding South-Africanism and at the same time retaining membership of an organization in a wider sphere. This, he said, was only an aspect of the same problem—expressed as the difficult problem of reconciling the ideal of empire with that of the individual nation. It had been thought worth while to solve that problem, and a solution had been found. He hoped the medical success would be an inspiration and an example to some of those who were dealing with the problem in the wider sphere.

Dr. A. J. Orenstein, President of the newly-formed Medical Association of South Africa (British Medical Association), in replying to the Administrator, said that the Association was very young, being just eleven weeks old, but he trusted it was a well born babe. Speaking with regard to expressions which were too often in the mouths of people who were ill-informed, he pointed out that a medical association was not in any sense a trade union. It could not be so, for the members of the medical profession recognized to the full that they were servants of the public, and acted up to that conception. What profession other than medicine could point to such self-sacrifice? The ship that was now starting on its course had been built by the British Medical Association, from which it was not lightly parting. It was retaining a link which was not to be temporary, for the profession in South Africa recognized, to its credit, the deep debt it owed to the British Medical Association. The link retained was the result of a plan which wounded no one, and yet retained for the profession in the Union a place in the great medical commonwealth of the British Empire, aided it with the strength derived from alliance with the greatest medical association in the world, and increased its power for service to the public. Though the profession lived by the ills of other people, its main energies were concentrated on the destruction of the means by which it lived.

England and Wales.

Health of Manchester.

The annual report for 1925 of Dr. R. Veitch Clark, medical officer of health for Manchester, estimates the population of the city for the year at 758,235. The birth rate of 18.6 continues the recent decline. The death rate of 14.4 shows a slight increase over preceding years. The infantile mortality rate of 95.77 per thousand births is, with one exception, the lowest on record. The number of cases of diphtheria was above the average. Of the contacts swabbed 5.7 per cent. showed diphtheria bacilli. Of the 65 cases of enteric fever which occurred 40 were typhoid and 25 paratyphoid B, most of the latter being in one institution. Encephalitis lethargica was less prevalent than in 1924. An inquiry which was made regarding the relationship of this disease to influenza and epidemic hiccough produced no positive evidence. The notifications of pulmonary tuberculosis during the year were 1,504, of non-pulmonary 622. An investigation was carried out on the Weisz urochromogen test for pulmonary tuberculosis. The conclusion from the data received is that the test is of value in assisting diagnosis. A large number of cases of pemphigus neonatorum occurred during the first six months of 1925, and the disease was accordingly made notifiable for six months as from September 10th. From that date to the close of the year 83 notifications had been received. Among 2,269 cases of scarlet fever admitted to Monsall Hospital the mortality rate was 2.28 per cent.; a ward has been equipped at the hospital for the ear complications of this disease. Except in the few instances of massive necrosis of the temporal bone the persistence of otitis media in scarlet fever appears to be due to infected tonsils and adenoids; thorough removal in such cases is therefore justified. It is added that the omission of syringing of the ear has materially improved results. All cases of scarlet fever are submitted to the Dick test; the Schultz-Charlton test is also employed; both have been found of service. Scarlet fever antitoxin definitely improved the condition of six early uncomplicated cases, but a toxic case treated with antitoxin on the second day died on the fourth; the number of patients admitted to Monsall with diphtheria was 854. Their case mortality rate was 8.36 per cent. There were 29 tracheotomies with 14 deaths. All persons entering the nursing service of the hospital are Schick-tested, and, if reactors, immunized against diphtheria.

There were 144 admissions of puerperal fever; of these 23 died, a case mortality of 15.23 per cent. Treatment was by lymph drainage of the uterus for the local condition, and by this method, together with chemotherapy and immuno-blood transfusion, for the acute blood infections. The results of lymph drainage at the hospital were uniformly good; the ultimate results of immuno-transfusion were as uniformly disappointing. The chief veterinary officer for the city states, in his account of work, that 8.2 per cent. of milk samples from farms outside Manchester were tuberculous, but that all the large farms, and some smaller ones, have now installed pasteurization plant, so that at least half the milk distributed in the city has been rendered safe for consumers. The progress report on cancer by the medical officer of health summarizes the programme of the Cancer Committee. The main line of experimental research at present contemplated is in connexion with the origin and prevention of mule-spinners' cancer, now well known as a disease of the cotton industry, whose causation was recently discussed by the Manchester Pathological Society.[1]

LEEDS MEDICAL SCHOOL.

Dr. J. B. Baillie, vice-chancellor of Leeds University, delivered an address on medical research at a congregation at the conferment of degrees on December 22nd, 1926. He said that graduation did not abolish the need for study because the scope for the functioning of the spirit of inquiry was inexhaustible. The history of medicine was strewn with wrecks of abandoned theories, and the heresies of yesterday were the orthodoxies of the present. An open mind was the only passage through which the light of science could enter. Dr. Baillie thought that a new beginning in the process of medical science was dawning, and the medical practitioner had to take all science as his province. The extension of the spirit of scientific research in the University of Leeds, including the provision of an entirely new department of experimental pathology, was a most welcome advance, and great gratitude was due to the generosity of Yorkshiremen who had made possible this asset to medical education. Dr. Baillie alluded to the coming loss by the University of Sir Berkeley Moynihan, whose enthusiasm and standard of achievement would be a living inspiration to his pupils, and an abiding example in the days to come.

CARLISLE SURGICAL APPOINTMENT.

Following on the death of Mr. C. Balfour Paul, Mr. James N. Jackson Hartley has been appointed surgeon to the Cumberland Infirmary, Carlisle. Mr. Hartley is at present assistant surgeon to the Edinburgh Royal Infirmary. He graduated at the University of Edinburgh in 1913 with first-class honours, when he was awarded the Ettles Scholarship, Annandale Gold Medal in Clinical Surgery, and Buchanan Scholarship in Gynaecology. During the war he was attached as an officer of the R.A.M.C. to a special hospital at Etaples for the purpose of investigating newer methods of wound treatment, and received the O.B.E. in recognition of these services.

THE CARE OF CRIPPLES IN SHROPSHIRE.

King Manoel, on December 17th, 1926, opened a new ward for infants at the Shropshire Orthopaedic Hospital and Agnes Hunt Surgical Home at Oswestry. Dame Agnes Hunt, the founder of the Home, was present, and Sir Robert Jones, in an address, mentioned the great interest taken by King Manoel in all forms of the treatment for cripples and the disabled. After the opening King Manoel visited Shrewsbury and spoke at a public meeting organized by the Shrewsbury Cripples' Care Committee. Sir Robert Jones, who also addressed the meeting, referred to the national scheme for the prevention, cure, and training of cripples. The preventable diseases of tuberculosis and rickets were concerned in 70 per cent. of cases of crippling, and further energetic steps were needed to eradicate these two causes. Continuity of treatment and proper after-care were essential, and new hospitals for children must be built in the country and not in the towns. After-care clinics were also required to provide supervision by experts for patients who had received treatment in residential institutions. Both King Manoel and Sir Robert Jones paid tributes to the pioneer work of Dame Agnes Hunt, who spoke subsequently on the importance of hygienic milking methods and the erection of houses with more open surroundings. Cripples, she said, needed to be given a trade so that they might attain a measure of independence.

Scotland.

ANIMAL RESEARCH IN EDINBURGH.

AN appeal has been issued, signed by Lord Balfour as Chancellor of the University of Edinburgh, Sir John Gilmour (Secretary of State for Scotland) as the Lord Rector, and Sir J. A. Ewing as Principal of the University, in regard to the subject of research in animal breeding under the control of the University and the Edinburgh and East of Scotland College of Agriculture. Mention is made of the recent gift by Lord Woolavington of £10,000 towards the endowment of a chair of animal breeding in the University of Edinburgh, and of the existence on a small scale since 1920 of a department conducting research on this subject. The International Education Board of New York, one of the Rockefeller Foundations, has now made a contingent offer of £30,000 towards the building and equipment of this department. This offer is conditional on a like amount being obtained from other sources and on the provision of certain funds for maintenance. The Government, through the Development Commissioners, is prepared to provide a substantial part of the required funds, and the University will do what it can, but a further sum of £30,000 is still required as an endowment to enable the scheme to be realized, and the offers of the International Education Board and of the Government do not become effective until this is guaranteed. The present appeal is therefore issued to persons interested in the development of stock breeding, agriculture, the encouragement of science, and the establishment of a school of animal genetics which may become the most important in Europe. Subscriptions may be intimated to the Secretary of the University of Edinburgh.

GLASGOW WESTERN INFIRMARY.

At the annual meeting of Glasgow Western Infirmary Colonel J. A. Roxburgh, who presided, said that the hospital had not escaped the industrial troubles of the past year, and the ordinary income for the year was not expected to exceed £67,000, as against £73,000 for the previous year. There was an estimated ordinary expenditure of £84,000, and the infirmary would be faced with a deficiency of £17,000. There had been an increase in the work done, attendances at the out-patient department especially constituting a record with the number of 170,000. The managers had been enabled through the receipt from the trustees of the late Robert Donald of £12,000 to make a full-time appointment for cancer research; Dr. A. A. Charteris had been appointed to this post, and was working in connexion with the professors of pathology and bacteriology at this subject. The infirmary was at present much in need of a new *x*-ray department, and the managers were making a special appeal for this purpose.

Ireland.

HISTORY OF THE ROTUNDA HOSPITAL.

THE progress of the Rotunda Hospital during the last thirty years was the subject of an address by Dr. A. Madill, president of the Section of Obstetrics and Gynaecology of the Royal Academy of Medicine in Ireland, on December 10th, 1926. In the course of his address Dr. Madill mentioned the failure to reduce morbidity in the hospital and to improve on the eclampsia figures of Dr. Tweedy. He also referred to the poor results of Caesarean hysterectomy in cases of concealed haemorrhage, and emphasized the importance of the advance towards safety since the introduction of pubiotomy and Caesarean section. During the discussion Sir William Smyly described the change since the time when sterilization was only employed for instru-

ments, and no efforts were made to cleanse the patients from the dirt brought with them into the hospital from their homes. The majority of the pupil midwives then were not residential, and regularity of attendance and discipline were very defective. Dr. Gibbon FitzGibbon referred to the effect of the introduction of the motor car in bringing to the hospital serious cases from outlying districts; in this way, he thought, some of the present high morbidity and mortality among hospital patients was to be explained. The last six years compared unfavourably with the preceding fifteen years. The increase in the use of forceps and in the induction of labour might also be a factor in causing morbidity. He added that the Dublin maternity hospitals were responsible for 70 to 75 per cent. of all the midwifery of the city. The institution of the ante-natal department by Dr. Gibbon FitzGibbon was mentioned by Dr. Bethel Solomons, with particular reference to the prevention of eclampsia by the early diagnosis of albuminuria.

PEAMOUNT SANATORIUM.

The Committee of Management of the Peamount Sanatorium, in its report for 1925, states that the number of patients sent by the different tuberculosis and insurance committees was greater than in 1924. On January 1st, 1925, there were 196 patients in the institution; 653 patients were admitted, and there remained at the end of the year 199 patients. The sanatorium is supported by the contributions given by the different committees who send patients for treatment—namely, £2 2s. a week for adult patients and £1 17s. 6d. for children. There is no other source of income, and the committee must meet all expenses out of the contributions received for the patients. This it has been barely able to do during the year under review, for after treating 849 patients at a total cost of £23,267 the accounts showed a balance of income over expenditure amounting to less than £6. The committee consider this margin very small, as it has no funds in hand or capital sum for any emergency or unusual expenditure. The cost per patient per bed at Peamount, although situated twelve miles due west from Dublin, is lower than any of the Dublin clinical hospitals under the auspices of the Dublin Hospital Sunday Fund, where the medical staff is voluntary and where linen guilds supply all linen, etc.—a considerable item of expense in any such institution. The necessary repairs to the different pavilions, shelters, dining-hall, administration building, laundry, and electric plant were carried out so as to keep these buildings in proper order, and in some cases much needed renewals and improvements were effected. As the seven pavilions, doctor's house, dining-hall, and thirty shelters are wooden structures the expense of keeping these in good repair necessarily amounts to a large sum yearly. The resident medical superintendent, Dr. Sheehan, in his report makes special reference to advanced cases sent for treatment. The committee, while realizing the difficulties tuberculosis officers labour under, considers it unfair both to the patients and the institution to send advanced cases for treatment. About one-fourth of those admitted were more fitted for institutions for advanced cases than for Peamount. The committee notes with pleasure that the Minister of Local Government and Public Health is taking steps to have suitable institutions established for such cases. Another point emphasized is the want of after-care committees in each county from which patients are sent; the Central After-Care Committee can only deal with patients in and about Dublin. Prior to the great war the Women's National Health Association had established such committees in each of the counties sending patients. The most satisfactory part of the work at Peamount is the good result obtained from the treatment of children of school age in a self-contained children's pavilion. Dr. Sheehan states that this pavilion is the brightest spot in the grounds, and the high percentage of discharged patients with the disease arrested has fully justified the committee in catering specially for children. With the educational and recreational facilities provided for under medical supervision the occupants enjoy their stay in Peamount. The committee, on the recommendation of the medical staff, has given an order for two ultra-violet lamps, which are expected to be installed early in the New Year.

Correspondence.

PRACTITIONERS OF PATHOLOGY.

SIR,—May we beg the courtesy of your columns to draw attention to the fact that a meeting will be held at the London School of Medicine for Women at 2.30 p.m. on Friday, January 7th, for the purpose of considering the advisability of forming a society to represent the interests of those engaged in the practice of pathology?

There is general agreement among those engaged therein that the conditions of pathological practice throughout the country are very unsatisfactory and are in danger of becoming more so. The competition for pathological work on the part of subsidized institutions of various sorts, both academic and commercial, and of local authorities and the resultant cutting of fees is threatening to reduce the remuneration from pathological work to such an extent that little inducement will be offered to competent men to enter this important branch of medical practice. The present state of pathological practice, moreover, offers little encouragement to non-teaching hospitals to attempt to bring their pathological departments to a state of efficiency. It is in the general interest of medicine that pathological knowledge should be as widespread as possible and not confined to the teaching centres.

Up to the present pathologists as a class have had no organization to represent their interests. The need for such a body appears to be urgent, and we therefore hope that all those interested who can manage to do so will attend the meeting.—We are, etc.,

*** The Council of the British Medical Association, at its meeting on December 15th last, had before it the report of the special Pathological Committee appointed to consider this subject, and a full account of the discussion will be found in the Proceedings of Council published in the SUPPLEMENT this week.

MIGRAINE AND ACETONURIA.

SIR,—Dr. Fawkes has shown the way (BRITISH MEDICAL JOURNAL, December 18th, 1926, p. 1176) to a truer understanding of migraine. I have been familiar with the facts he has noted for a long time, but have been slow to make them more widely known.

One of my children used to suffer from attacks of cyclic vomiting associated with acetone in the breath, attacks which finally culminated in acute appendicitis, and were completely cured by the removal of the appendix. My wife, who, like many women, has an acute sense of smell, learnt to recognize the acetone in the breath, and I taught her how to abort the attacks by giving immediately large doses of magnesium carbonate and glucose.

From childhood I have suffered from typical severe migraine. These attacks usually came on on Sundays, when I was able to relax after periods of severe overwork during the week at the hospital. On Saturdays

I would notice areas of exquisite superficial tenderness on the inner side of one arm, on the Sunday morning I would fail to obtain the usual alvine evacuation, and during the morning a severe attack of migraine would appear on the same side of the head as the area of superficial tenderness on the arm, with vomiting and giddiness. That evening, or next day, I would pass a foul, fatty stool of a peculiar odour, which I learnt to recognize, and the migraine left me. My wife noticed that on the Saturdays my breath was full of acetone, and on Sundays she could detect the acetone as I entered the room.

This set me thinking, and made me realize that the poison which produced the migraine must be associated with acetone bodies in the blood, but, though acetone was so marked in the breath, I never could detect them in the urine by the ordinary tests. I came to the conclusion that the cause of migraine must really consist in a failure of the liver to deal with certain bodies in the food—probably fats. I therefore watched my diet and found that the substances in the food, the failure to detect which by a tired stomach and liver induced migraine, were of three kinds:

1. The fats of meat, particularly beef, mutton, pork, veal, duck, and bacon. (Butter, cream, and suet were harmless.)
2. Coffee and chocolate.
3. Spirits, particularly whisky.

I found that by cutting these articles clean out of my diet attacks of migraine became of rare occurrence.

If my wife noticed acetone in my breath I could always tell her that I had at the moment the warning signs of a migraine—namely, areas of superficial tenderness on the arms. I learnt then to take large doses of sodium bicarbonate, starve myself for twenty-four hours, and take a Seidlitz powder. These measures usually aborted the attack. I have since used this knowledge in helping a number of colleagues and patients who have told me that they suffered from migraine.

It is time to call the attention of the biochemists to these observations. If they will carry out observations on the breath, blood, and urine of migraine sufferers, and perhaps apply tests for deficient liver function, I believe they will find that in this direction lies the poison that causes migraine.

Migraine is, in my view, brought on by a temporary functional disorder of the liver. It is predisposed to by any factor which causes muscular or mental fatigue, such as overwork, eye-strain, sitting for a long time in a crowded and badly ventilated room, and is induced by a tired stomach and liver unable to deal with too large a dose of certain animal fats, coffee, chocolate, and spirits. The temporary constipation followed by the passing of a foul stool is the result of a failure on the part of the liver to secrete healthy bile into the intestine. The attack is ushered in by acetone in the breath, which, if detected in time, can enable adequate measures to be taken to abort the attack—namely, the exhibition of alkalis, starvation, and a Seidlitz powder.—I am, etc.,

December 21st, 1926. CONSULTING SURGEON.

SIR,—I can confirm Dr. Fawkes's statement (BRITISH MEDICAL JOURNAL, December 18th, p. 1176) that examination of the urine of children, and frequently of adults, suffering from migraine and recurrent vomiting shows the presence of acetone bodies, but my experience is that if the blood is also examined an abnormally low sugar content is generally found, thus accounting for the beneficial effect of glucose to which Dr. Fawkes refers. The hypoglycaemia met with in this type of case is usually not transitory, like the acetonuria, and can be detected in the interval between the attacks.

Breeding experiments with mice, which Mr. Howard and I have been conducting for some time, have demonstrated that hypoglycaemia may be hereditary, but the results of numerous analyses of the blood, urine, and stools which I have carried out in cases of recurrent vomiting and migraine suggest that intestinal disturbances are a common exciting cause, as Dr. Fawkes points out. The hereditary factor cannot, of course, be treated, but much can usually be done to prevent the attacks by keeping up the glycogen store in the liver and by taking suitable measures to improve abnormalities of intestinal digestion and absorption revealed by analysis of the faeces and urine. In many instances it is only by means of such analyses that the exciting cause can be discovered.—I am, etc.,

London, W.1, Dec. 18th, 1926. P. J. CAMMIDGE.

THE PROPHYLAXIS OF TUBERCULOSIS IN TOWN CHILDREN.

The Grancher System.

SIR,—In your issue of November 7th, 1925, under the above heading, was published a letter from me in which I gave details of a method employed by the Hastings Tuberculosis Care Committee for dealing with poor children threatened with, or in an early stage of, tuberculosis. The plan consists in placing them in selected country cottages and keeping them during their stay under careful supervision. I should like, if I may, to say a little more on the subject, in the light of subsequent experience, in answer to questions that are frequently put to me by word or letter.

As I then stated, the scheme was started in France by Dr. Grancher and now is known by his name. It was described by Professor Armand Delille at the Tuberculosis Conference held in London in 1921. He told us that 2,300 tuberculous children from Paris alone had been placed in rural peasant cottages with excellent results. It had been adopted in England to a limited extent by some tuberculosis care committees other than our own, but notably by the London County Council, who at the beginning of last year decided to put into practice a scheme for the removal of children from heavily infected and overcrowded areas, during the terminal stage of a dying case of pulmonary tuberculosis in the family, and boarding them out, this provision being undertaken in co-operation with the Invalid Children's Aid Association. The secretary of that society states (October, 1926) that "the scheme would appear to be a great success up to the present time." I think it can be shown that this plan has special advantages of its own, and that if it were more generally practised a much larger number of children suffering from the premonitory symptoms of pulmonary tuberculosis, or in imminent danger of catching it, could be removed at once from the source of infection and placed in a position of safety than is possible at the present time.

The paramount importance of grappling with this disease in the earliest stages and in childhood is unanimously accepted. Sir George Newman writes, "We cannot rightly deal with tuberculosis apart from the proper treatment of the disease in infancy and childhood, possibly the chief age-period of its infection and invasion, perhaps even of its immunization, and certainly the opportunity for its treatment" (*An Outline of the Practice of Preventive Medicine*, p. 49). From the same work we learn that "there are 600,000 children in England . . . debilitated and anaemic, malnourished, stunted, and weakly." A large number of them would be children of the poor either suffering from tuberculosis in an incipient form or liable at any time to contract the disease. No doubt the best plan would be to send all such cases to residential open-air schools, if it were possible to do so; but, apart from the financial difficulties, the accommodation in these establishments is for less than 6,000—not 1 per cent. of the figures mentioned above. Many of the children now sent to sanatoriums could be promptly dealt with in this way at about one-quarter of the cost. The economic advantage bears no comparison with other methods. Our expenses are 11s. 3d. per child per week, and part of this is sometimes refunded by the parents. The children live with people of their own social class, and they are free and happy, as their letters home constantly testify. Wherever possible a married couple, with no children of their own, are selected, and the parental, more especially the maternal, instinct plays a most important part. The care, attention, and good living that the children receive are often surprising and out of all proportion to the money paid for them. Such is the vitality of childhood that they respond at once to these altered conditions and continue to improve. During more

than seven years' experience I remember but one exception to this rule, and in that instance the case was complicated by asthma. The method is now in such good repute in this locality that the parents' consent is readily obtained. Judging from my correspondence, this appears to be looked upon as a difficulty, but it seems to be more frequently anticipated than real. Our work in this direction is done in conjunction with the Guardianship Society of Brighton. Their secretary, a lady who has been engaged in this capacity for many years, and an enthusiastic worker, writes, "There is a great future, I believe, for boarding out; it is the organization that is required. . . . We are trying to start in Kent, which should be an easier county than Sussex."

The following is an excellent example of success obtained in this way, but it is also recorded on account of the striking evidence it affords that a child suffering from pulmonary tuberculosis may, if cured, ultimately obtain an immunity from the disease.

In January, 1918, George P., aged 9½, was attending school. He had been delicate since the age of 4, when he suffered from a tuberculous abscess of the neck. His parents and two younger brothers were healthy. His sister died of tuberculous meningitis. He lived at that time in his present home, which is situated in one of the worst localities of a poor neighbourhood. The house consists of three rooms built one above another. It is old and dilapidated and is placed in a court that branches off from a narrow street. It faces north, and the opposite dwelling is distant only 5½ yards. The back of the house is composed of a brick wall with no windows or doorway, consequently the room gets no sunshine whatever. The light is always dim and the air feels stagnant and heavy. The living room measures 3½ yards by 3 yards. It is used also for cooking, as a scullery, and for washing and drying clothes. The boy was sleeping with his two brothers in the top room, which is only an attic, with one small window. He remained indefinitely unwell until the middle of 1919, when the tuberculosis officer examined him at the dispensary and reported dullness and crepitations at the right apex.

He then came under the notice of the Hastings Tuberculosis Care Committee, who sent him at once to a country cottage. They also reported the condition of his home to the sanitary authority and advised the parents to find another dwelling. This they have not done, the reason assigned being their inability to pay the rent of the recently constructed houses.

The lad's history is a repetition of staying for a while in the country and rapidly improving, returning home, generally at his mother's request, and almost immediately relapsing. This continued until 1922, when he came home looking remarkably well, and from that time onwards he has not relapsed and has worked with a local decorator without intermission up to the present date.

He was examined in November last by the tuberculosis officer, who reported him as being "perfectly well," notwithstanding that he has lived in the same insanitary environment in which he contracted the disease; and, to make matters worse, his father, in 1925, developed pulmonary tuberculosis, for which he stayed last year in the county sanatorium. During this year he has been at home undergoing "domiciliary treatment." His sputum is positive, he has lost 28 lb. in weight, and his incapacity is given as 100 per cent.

Therefore this lad can now live and thrive in the worst of insanitary conditions, which had previously reacted unfavourably, and in daily contact with an advanced infectious case. I submit that the history of this patient offers the strongest presumptive evidence in support of the view that an immunity has been acquired.—I am, etc.,

W. BOLTON TOMSON, M.D.,
Vice-Chairman of the Hastings Tuberculosis Care Committee

December 14th, 1926.

LEPROSY: ITS TRANSMISSION AND TREATMENT.

SIR,—I have read with much surprise the letter from Sir Leonard Rogers on the subject of the treatment of leprosy, in your issue of December 18th, 1926 (p. 1195). Sir Leonard seems to confuse the vaccine, of which I gave the composition in the BRITISH MEDICAL JOURNAL of December 4th (p. 1034) with the leprolysines, nastines, etc., for I am wholly unaware of the existence of any antileprous vaccine comparable with mine and in use "for several decades." Some few months before Sir Leonard Rogers's Croonian Lectures of 1924 an International Conference of Leprosy was held in Strasbourg, at which Sir Leonard was official delegate for India; the conclusions announced at the end of the debates of this conference by the president, Professor Jeanselme, were: "that there is not a specific medication for leprosy" (*Conf. Int. de la Lèpre*, 1923, p. 501). "We cannot say that the hopes which Rogers, Hollmann, Dean, Brocq, and Pomaret had built were fulfilled" (ibid., p. 503).

It is probable that certain preparations of chaulmoogra have some therapeutic action on certain forms of leprosy when it is in its initial stages, but this action seems very unreliable and limited in scope.

During this year, after the publication of my lecture in the *Transactions* of the Royal Society of Tropical Medicine and Hygiene (January, 1926), I have received a large number of attestations from leprologists as to the poor result obtained by the use of chaulmoogra preparations in leprosy, notably from the director of a leper institution in India with 550 cases under his charge. My own experience is to the same effect: I have never obtained with these preparations the smallest success worth reporting, and in some cases the disease was actually aggravated by their use. It is fair, however, to say that the majority of my cases were not in the initial stages.

In conclusion, I would say to Sir Leonard Rogers that I also have been able to clear eruptions of leprosy in initial stages with solutions of oil of turpentine, and carbolized oils, and, most effectively of all, with amino-arseno-phenol, which I regard as a fairly efficient lepricide in early cases. But all these forms of treatment are non-specific, and their action seems limited to certain quite early phases of the disease.—I am, etc.,

London, W.2, Dec. 19th, 1926. J. HASSON, M.D.

SIR,—In answer to Sir Leonard Rogers (December 18th, 1926, p. 1195) I may say that I was for some seven years, and until quite recently, editor of the Skin Diseases Section of the Tropical Diseases Bureau, and that in condemning the chaulmoogra products I was relying upon reports which came under my notice from countries where lepra is endemic, and not only upon the "general experience of London dermatologists," although I cannot, of course, subscribe to his implication that that experience is worthless. I might retort that the results from the use of these preparations seem propitious in proportion to the remoteness of the reporter, and medication described as efficacious in Fiji is demonstrated to be a dud in London. Sir Leonard Rogers seems to imply that essentially the same method as was used in my case had been used "for several decades either as tuberculin, which gives a reaction in leprosy, or as killed lepra bacilli." I submit that there is far more difference between the method mentioned by me and the methods so erroneously cited as identical by Sir Leonard Rogers, than there is between the use of the products of chaulmoogra oil, recommended by Sir Leonard, and the use of the oil itself, which has been the staple drug employed in the treatment of leprosy in the East, not "for decades," but for centuries. That chaulmoogra gives very unencouraging results is abundantly evident from the despair with which leprosy cases are usually confronted in countries where the disease, and this treatment, are most prevalent. The argument which Sir Leonard uses to belittle the value of the new vaccine is tenfold more effective against his own pet preparations.—I am, etc.,

London, W.1, Dec. 20th, 1926. E. GRAHAM LITTLE.

EARLY TREATMENT OF ENCEPHALITIS LETHARGICA.

SIR,—The article in your issue of December 18th (p. 1190) on "A unit for the residua of encephalitis lethargica" seems to indicate that the plan for dealing with these serious conditions is to make special arrangements for investigating and treating the late stages. By the time, however, sequelae have developed, especially if doubtful cases are ignored, some of the factors operating in the first instance have disappeared, except in so far as their consequences are still evident. Surely the stage at which such a disease should be studied is at its commencement. The arrangements made seem to continue the fallacy pointed out by the late Sir James Mackenzie, when he showed that usually it is only the general practitioner who can discover the causes of disease, and not a pathologist working in a *post-mortem* room two, three, or four years after the primary agents have gone, leaving perhaps no trace.

It is a deplorable fact that many cases of encephalitis lethargica are treated in a cavalier manner, dubbed influenza, and little or nothing done. This still goes on, although it is known that many of the cases with serious consequences do not seem bad at first; some do not see a doctor at all, and are only discovered later. But the first day may be the only time it is possible to detect the primary infection, so virulent, and so active in penetrating the cribriform plate of the ethmoid.

As some patients die in a few days no time is to be lost. The site of infection must be investigated thoroughly. Those of us who see the after-results in the form of dementia praecox, which would not have occurred otherwise, apparently inexplicable forms of manic-depressive mental disorder, and mental defect, which does not date from birth, know that even then swabs of the nose and throat nearly always show various pathogenic organisms. Even if these are only secondary infections they supply material valuable for treatment in the later stages, and indicate how much might have been effected at first by active local and general treatment for combating infection. But we have also noticed that many serious sequelae are often associated with other abnormal conditions, such as diseased teeth, and toxaemia of the alimentary tract. These must have been present at first, and may have determined the issue. But they are scarcely ever investigated, or at the most by a perfunctory question as to whether the bowels act every day. Further, it must be realized that the infected areas are at the base of the brain. Disorders of emotion are therefore much more common than any intellectual failure, especially at first. Usually this is not taken into consideration at all.—I am, etc.,

Birmingham, Dec. 16th, 1926. W. A. POTTS, M.D.

SANATORIUM TREATMENT.

SIR,—I have no claims to be considered an expert in statistics, but I have a certain knowledge of the clinical course of pulmonary tuberculosis in the district where I work, and I shall confine my remarks to the incipient cases considered in Dr. Stocks's memoir. I believe that the sanatorium-treated group was a selected group of patients with progressive disease for the following reasons.

(1) The fact that only 25 per cent. of incipient cases received sanatorium treatment suggests strongly that some method of selection was employed. The tuberculosis officers would urge treatment in those cases where it appeared to be most necessary: the patients would be more likely to accept their advice if they felt too ill to follow their normal mode of life.

(2) A study of the graphical representation of the progress of incipient cases on page 415 of Dr. Stocks's memoir supports this view. The sanatorium-treated group shows a higher percentage of "dead" and "progressive" cases at every single time period of the six years under review. This suggests to Dr. Stocks that sanatorium treatment had a bad effect: it suggests to me that this group contained a high proportion of patients with progressive disease.

(3) The patients were not reclassified at the time of their admission to the sanatorium.

(4) The data in the memoir support this view so far as they go. The difficulty is that these data are so inadequate as to be merely straws which show which way the wind is blowing. For example, the sanatorium-treated group shows a higher proportion of cases with marked systemic disturbance. This systemic disturbance was assessed apparently on a single observation of the temperature and pulse rate. If observations on the morning and evening temperature had been recorded for a fortnight before classification, they might well show a substantially higher proportion of cases with systemic disturbance in the sanatorium-treated group. If this was done there is no record of it in the memoir: if it was not done, the authors of the memoir are not in possession of the necessary data to attempt to assess the systemic disturbance. I submit that this factor alone might reverse the conclusions of the authors.

Again, the weights of the sanatorium-treated group fell on an average half a pound before admission, while the non-sanatorium-treated group increases by about half a pound during the same time interval. Dr. Stocks regards these differences as insignificant, but indeed he has already shown in the memoir that nutrition has only a small influence on progress (pp. 438-440). Yet in his letter of December 11th, 1926, he says that the existence of selection was precluded by the most accurate possible method—that is, a study of the weight curve. I concede his point that the differences of weight were insignificant in the different groups and advance further that the weighing machine is unable to show whether a patient is suffering from incipient "open" tuberculosis or incipient "closed" tuberculosis. This is shown by figures from the Forster Green Hospital. During 1921, 57 patients, classified as "incipient" on admission, were discharged. Of these, 24 had tubercle bacilli in the sputum, and their average weight on admission was 8 st. 11 lb.; their average gain of weight in the sanatorium was 8 lb. The other 33 patients, who had no sputum or in whose sputum no tubercle bacilli were found, had an average weight of 8 st. 10 lb. on admission and an average gain of weight of 9½ lb.

This leads one to inquire as to the proportions of T.B.+ and T.B.− cases in the sanatorium-treated and non-sanatorium-treated groups. But it has been pointed out already by several of your correspondents that this information is not available in anything like a complete form. Both in the memoir and in the ensuing correspondence Dr. Stocks has not faced the fact that the presence of tubercle bacilli in the sputum is the most important single factor in prognosis. Throughout the statistical tables two groups of cases with quite different prognosis are mixed in unknown proportions. As there are no complete records of sputum examinations, these groups cannot be disentangled by any statistician, however expert.—I am, etc.,

B. R. CLARKE, M.D.,
Medical Superintendent, Forster Green Hospital, Belfast.

December 14th, 1926.

CHOLECYSTOGRAPHY.

SIR,—In the issue of the BRITISH MEDICAL JOURNAL for November 6th (p. 864) I have noticed a letter from Mr. G. P. B. Huddy, M.S., F.R.C.S., on a fatality which occurred following the injection of sodium tetraiodophenolphthalein. So far as I know this is the only fatal case which might be considered due to the injection of tetraiodophenolphthalein. It has seemed to me advisable to call attention to the fact that not only was the dose nearly twice as much as the dose which my associates and I have recommended in our publications, but that also certain precautions which we have stated repeatedly as being desirable, if not necessary, were not taken in this case. Mr. Huddy states that the patient was given 5½ grams of sodium tetraiodophenolphthalein. The largest dose which we have given to a human being is 3½ grams, and we usually do not give more than 3 grams. We never give more than 0.06 gram per kilo of body weight. I cannot understand how Mr. Huddy could get the impression that 5½ grams was a suitable dose. In all of our publications we have advised strongly giving the dose in two injections about half an hour apart. By dividing the dose in this way a patient who happens to have an idiosyncrasy can almost always be detected before receiving the whole dose.

If the newer substance, which was recommended in my address before the British Medical Association, published in the BRITISH MEDICAL JOURNAL for October 16th, 1926, be used, a very much smaller dose can be given. We now use almost exclusively this new substance called phenoltetraiodophthalein, which is a chemical isomer of tetraiodophenolphthalein. A suitable dose of this newer substance for the average sized adult is 0.04 gram per kilo of body weight. We have never found it necessary, however, to give more than 2.5 grams of it to any adult. Since using this newer substance and exercising the precautions which we have always emphasized, we have had no serious toxic effects. This matter is taken up in detail in my article to which reference was made above. It should be mentioned also that only a pure drug should be used. Unfortunately at present it is impossible to exercise any kind of supervision or control over the manu-

facture of these substances; and probably, just as in the case of salvarsan, some deaths will occur from the use of impure products.

I feel very greatly indebted to Mr. Huddy for publishing the details of this fatal case. Certainly any catastrophe like that should be given full publicity. Cholecystography is a comparatively new procedure and it is possible that more deaths may occur. My only purpose in writing this letter is merely to point out the facts that the dose which was given to this patient of Mr. Huddy's is nearly twice the size of the maximum dose which we have ever used in a human being, and also that certain precautions which we have very carefully taken pains to recommend in most of our publications were disregarded in this case. For these reasons it would seem to me unfair to the method to have any reader conclude from the report of this case that the method, when properly carried out, is essentially one that is dangerous to life. However, I do not wish to give the impression that it is entirely free from danger. In the case of the intravenous injection of any substance meticulous care is necessary as regards dosage, preparation of the solution, method of administration, etc. Finally, the fact remains that several thousand people have received intravenous injections of tetraiodophenolphthalein and of its isomer, phenoltetraiodophthalein, without a death when the procedure has been carried out with the precautions which we have urged.—I am, etc.,

EVARTS A. GRAHAM,
Professor of Surgery.

Washington University, St. Louis, U.S.A., Dec. 1st, 1926.

THE AGE INCIDENCE OF RHEUMATISM.

SIR,—Recent correspondence has directed attention to the importance of rheumatism as a factor in invalidity and mortality statistics, and the question therefore arises of the extent to which the disease, and more particularly its cardiac complications, are prevalent among the various groups of school children medically examined by the local education authorities. Taking the time that the symptoms of rheumatism begin to appear to be about the fourth year of life, it has been found, from a survey in this district extending over several months, that the disease and its cardiac complications were present in the following percentages:

Age Groups.	Rheumatic (early symptoms).	Cardiac Complications.
5 years	... 15.1	... 5.7
8-9 years	... 10.4	... 7.7
12 years and over ...	... 5.7	... 13.2

These figures are self-explanatory, and, while different areas may present different percentages, it would appear that, although preventive or curative measures could be undertaken with most prospect of success in "entrants" and would no doubt be amply repaid, the problem is not one of the school medical service alone, but invites the co-operation of parents, sanitary authorities, guardians, and probably other organizations.

From the point of view of the school medical service, the difficulties of efficiently dealing with the whole problem of rheumatism in the school child are undoubtedly real, and I think the gravity of the situation calls for further effort and investigation.—I am, etc.,

Barking, Dec. 15th, 1926. K. SIMPSON, S.M.O. and M.O.H.

TREATMENT OF SYNCOPE.

SIR,—It is in the knowledge of most practitioners that pregnant women are prone to faint, especially during the first three or four months; more especially is this so when a hard instrument, such as a sound or curette, is introduced into the cavity of the uterus. I once diagnosed pregnancy when told by a fellow practitioner that he had been frightened by a patient going into a dead faint after the introduction of a sound. This patient was suffering from an intermittent haemorrhage, so it is not such a good example; but she proved to be pregnant, as she aborted a week afterwards. Now in these severe fainting attacks, due to irritation of the abdominal nerves, when the patients really bleed to death into their abdominal blood vessels, there is one method of bringing them round which should be well known, as it is very old, and that is, immediately the death-like lividity of the face is seen by the medical attendant, to place himself between the legs and elevate the body on to his shoulders; the quicker and the more roughly this is done the better: the colour immediately becomes rosy, and the pulse is again felt at the wrist. Artificial respiration is worse than useless.

The same method applies to chloroform heart failure; whether there is ventricular fibrillation or not it always seems to answer. I have often seen apparently dying patients come round when this has been done. A.C.E. mixture is probably the most dangerous anaesthetic that can be used, no doubt because it does not sufficiently prevent reflex shock. I was warned against it as a student, and have since seen many bad cases of syncope under its use. If chloroform has to be used, as the handiest and most useful anaesthetic, as it is, in private practice, or a dental consulting-room, where ability to depart quickly after the operation is desirable, then give it as Dr. Frank Paul of the Liverpool Royal Infirmary used to teach. Drop chloroform on to the mask until the patient is losing consciousness; then use another mask with about half an ounce of ether on it, until the colour of the face becomes rosy and the breathing heavier; then again give chloroform freely until there is relaxation. By doing this struggling is to a great extent avoided, and a rapid induction is obtained which appears to be, practically, as safe as can be. In giving ether by the open method a few drops of ethyl chloride on the mask at the start saves ether, and makes for a rapid and comfortable induction.—I am, etc.,

Wallasey, Dec. 9th, 1926. F. WILLIAM INMAN, M.B.

MONGOLIAN DEFECTIVES.

SIR,—In the JOURNAL for December 4th (p. 1080) Dr. F. G. Crookshank has pointed out that in his opinion one of the arguments I used in my Henderson Lecture to prove that "mongolism" is a pathological condition and not atavistic is not valid. Even if that is so there are still so many facts to support my view, which is that commonly accepted, that very strong evidence would be required to make me change it. I regret that I cannot regard the homologies so learnedly and cleverly expounded in *The Mongol in our Midst* as providing such evidence. In a fairly large experience I have not come across the transitional cases, the mongoloids, of whom Dr. Crookshank writes, or rather I have never seen a person of average intelligence suffering from mongolism. On the atavistic theory they should be fairly common.

Dr. Crookshank claims that Gans has shown that "the brain of the Mongolian defective is distinguished by just those characters that distinguish the brain of the Chinese child and the orang." It may be that my imperfect knowledge of Dutch has misled me, but I think that is a very free translation of Gans's meaning and of his references to the work of Kurz and Kappers on Chinese brains. The homologies, which Sera has discovered, between Japanese and orang skeletons can obviously have no bearing on the nature of mongolism unless Mongolian defectives are genetically related to the Japanese or the orangs, which is the very point in dispute.

I do not think that anything is yet certainly known as to the nature of mongolism, and if we assume that it is atavistic we may conceal our ignorance from ourselves and possibly from some others, but we shall tend to stifle research along physiological and pathological lines, which is likely to lead us some day to the truth.—I am, etc.,

R. D. CLARKSON.

Royal Scottish National Institution, Larbert, Dec. 15th, 1926.

SURGERY IN GENERAL PRACTICE.

SIR,—For many months past one has read few professional papers, lectures, etc., by eminent surgeons which have not contained sneers at the "occasional surgeon."

Probably the occasional surgeon varies in skill and judgement, as indeed does the consultant and pure surgeon.

Nevertheless, I contend that the occasional surgeon serves a very useful function. In many, perhaps most, instances he is really keen on surgery, has a natural bent for it, and has served quite a thorough apprenticeship, but on account of financial or other reasons has not been able to "hang on" indefinitely at his own hospital awaiting a vacancy on the staff. Unless he has a good deal of confidence in his ability as a surgeon he will not dare to undertake major operations when he goes into general practice, for he knows that a few unsuccessful operations will do his practice as a whole a great deal of damage. He is therefore unlikely to undertake an operation unless he feels it to be well within his powers. His operative work takes up a deal of his time, for which he is not recompensed by adequate fees. It is not a good financial proposition, but it adds interest to his work.

Possibly the eminent surgeons who make public criticisms forget that they themselves one day performed their first major operation, probably with a good deal of trepidation, and perhaps it was not done as well as it might have been. Possibly, also, in their first few hundred operations they lost a life or two which a man of greater experience might have saved. Did this deter them from operating any more?

May I suggest that good surgery is not confined to "Harley Street" and that all Harley Street surgery is not good. It is not every patient who can afford Harley Street fees or who is within easy reach of it. Are we to "sit on" our cases of perforated gastric ulcer and fulminating appendicitis until we can get the services of a pure surgeon—perhaps twenty-four hours later and at a prohibitive cost? I know of many lives lost thus.

Personally I have not yet reached the position where I am called in to operate by my non-operating colleagues, but apart from eye and throat work I tackle all operations arising in my own practice unless they involve a technique with which I have had no opportunity of making myself familiar—for example, Wertheim's operation. I am not aware that my efforts have done anything but good, and I consider that my patients have reason to be grateful to me, as indeed I believe they are. I have been operating in general practice for over seven years and I have lately lost my first operation patient, and in this case I do not think that all Harley Street would have produced a happier result. Doubtless I have been lucky.—I beg, Sir, to *remain*

December 7th, 1926. AN OCCASIONAL SURGEON.

Universities and Colleges.

UNIVERSITY OF OXFORD.

THE Board of Management for the Francis Gotch Memorial Prize has awarded the prize for 1926 to Frank Hawking, scholar of University College. This prize, consisting of a bronze medal and £5, is awarded annually after examination to a member of the University who has worked in the Physiological Laboratory for at least three terms and has not exceeded fifteen terms from matriculation.

The following candidates have been approved at the examination indicated:

FINAL B.M., B.CH.—*Medicine, Surgery, and Midwifery*: M. D. Bower, C. S. Broadbent, J. G. A. Davel, C. W. Flemming, L. O. F. Fysh, A. H. Gale, C. L. Harding, R. A. Haythornthwaite, R. C. Hodges, O. Hooper, C. W. Hope-Gill, R. Illingworth, T. M. Ling, G. E. Macdonald, R. G. Macgregor, C. W. Mackenzie, P. C. Mallam, F. G. Parker, W. F. H. Ray, W. D. B. Read, D. A. Robertson, E. M. Wright, Grace Batten, Rosaleen L. Graves. *Materia Medica*: A. R. Bowtell, C. F. J. Cropper, R. C. Hodges, A. P. Kingsley, R. Nutt, H. G. Pritchard, L. E. Swaby, L. H. Thomas, J. W. de W. G. Thornton, Florence H. Johnson, Caroline E. MacNeice. *Pathology*: H. H. Aitchison, A. R. Bowtell, H. A. Byworth, G. Campbell, C. F. J. Cropper, J. G. A. Davel, C. R. Greene, R. M. J. Harper, G. L. Macdonald, J. K. Marshall, M. G. Pearson, L. T. Ride, H. G. Wells. *Forensic Medicine and Hygiene*: L. W. H. Bertie, W. H. Brown, R. T. V. Clarke, C. L. Cope, J. G. A. Davel, C. W. Flemming, L. O. F. Fysh, A. H. Gale, O. Hooper, C. W. Hope-Gill, R. Illingworth, G. L. M. Inkster, G. E. Macdonald, R. G. MacGregor, C. W. Mackenzie, R. C. Probyn-Williams, J. W. Pugh, W. F. H. Ray, D. A. Robertson, Grace Batten.

UNIVERSITY OF CAMBRIDGE.

THE following candidates have been approved at the examination indicated:

THIRD M.B.—*Part I. Surgery, Midwifery and Gynaecology*: R. G. Apthorpe, E. S. Bolton, H. T. Cox, A. T. Curnow, R. D. Curran, R. E. D. Dauncey, A. A. Digges La Touche, M. G. Fitzgerald, F. H. Gillett, H. K. Goadby, F. Goldby, V. C. J. Harris, J. A. Hartley, A. S. Hollins, F. S. Hubbersty, C. E. Kellett, F. Kellett, R. L. Lancaster, C. J. Laviers, R. M. B. MacKenna, B. W. S. Mackenzie, T. F. McNair Scott, S. R. Matthews, G. C. Milner, E. A. Nicoll, C. L. [illegible], G. V. Parker, R. Pearce, R. A. Phillips, C. L. Potts, L. W. [illegible] N. Rocyn-Jones, R. P. Ross, [illegible] Shackel, L. A. P. Slinger, [illegible] C. I. Tuckett, S. Tysgarnja, [illegible] C. E. Woodrow. *Women*: I. Caley, G. M. B. Morgan, K. A. Muir, C. J. Ormerod. *Part II. Principles and Practice of Physic, Pathology and Pharmacology*: A. Barnsley, P. G. Benthif, B. H. Burns, G. P. Chandler, A. B. Connell, J. W. E. Cory, F. M. Deighton, M. S. Dewhurst, H. M. Elliott, R. W. B. Ellis, V. H. Ellis, H. W. Gordon, E. J. Greenwood, J. C. P. Grey, T. L. Griffiths, W. S. Grove, C. H. Hilliard, A. J. Johnson, F. W. Law, A. V. Mackenzie, B. W. S. Mackenzie, R. Marnham, J. G. Milner, J. W. Monro, J. L. Morgan, J. Morris, R. T. Mummery, H. E. Nourse, G. E. Parker, C. P. Pinckney, C. G. F. Plumstead, J. D. Procter, J. H. Randall, D. Riley, F. C. Roles, C. J. L. Sharp, D. G. Shields, W. E. Snell, G. F. Taylor, F. H. A. Walker. *Women*: M. G. P. Reed, D. S. Tait.

UNIVERSITY OF DURHAM.

AT a convocation held at the College of Medicine, Newcastle-on Tyne, on December 18th, 1926, the following degrees and diplomas were conferred:

M.D. (*Practitioners of 15 Years' Standing*).—A. P. Cawadias, E. R. Griffiths.

M.S.—R. C. Brown.

M.B., B.S.—L. Barber, Ethel Browell, S. Carnofsky, W. A. Cairuthers, R. R. Dodd, D. Ewart, L. Livingston, M. A. S. Margai, A. T. H. Marsden, H. O. Martin, E. H. Moseley, J. Niman, H. O'Connor, R. Russell, A. L. G. Simpson, R. B. S. Smith, N. Spark, E. P. Tulloh, J. H. Weir, F. Young.

B.HY. AND D.P.H.—Doris Helen Mofyer, P. J. O'Connell, B. F. Tredre.

The following candidates have been approved at the examination indicated:

THIRD M.B., B.S.—*Pathology and Bacteriology; Materia Medica, Pharmacology and Pharmacy; Public Health; Medical Jurisprudence*: G. Kahn, J. C. V. Hindhaugh, J. H. Hudson. *Pathology and Bacteriology; Materia Medica, Pharmacology, General Principles of Therapeutics, and Pharmacy; Public Health; Medical Jurisprudence*: M. A. Gaffar.

UNIVERSITY OF LEEDS.

THE following candidates have been approved at the examinations indicated:

M.D.—J. Cardis, A. M. Clay, F. W. M. Greaves.

FINAL M.B., CH.B.—*Part I*: F. V. Allen, S. [illegible] Crossfill, H. W. Davis, J. Donovan, L. [illegible] L. Godlove, Dorothy Halstead, P. Hamp [illegible] Heseltine, H. Hopkinson, J. H. Khan, Esther M. Killick, W. E. L. Lawson, J. Leibermann, J. O'Donnell, T. L. Owen, N. Pyecroft, R. J. H. Raines, D. R. Riddell, Doreen M. Robertshaw, A. C. Shuttleworth, L. Silman, V. P. Squire, J. O. Terry, and J. E. H. West. *Part II*: Mary Lightowler, W. Milligan, A. L. Mitchell, A. Shufleder, R. P. Viret, and J. Walker. *Part III*: Rosie B. Becker, I. Berenblum, I. D. Black, T. H. Carr, G. F. Dimmock, J. S. Dinsdale, H. G. Garland (distinction in medicine), R. C. D. Hann, Marjorie Haynes, I. Kovolman, H. A. Ledgard, S. L. Lord, G. H. Lowe, T. H. Monies, G. Thompson, R. P. Viret, and J. Walker.

D.P.H.—G. R. Baxter.

DIPLOMA IN PSYCHOLOGICAL MEDICINE.—H. Edelston, K. C. L. Paddle, and J. Russell.

The West Riding Panel Practitioners' Prize in Medicine was divided between H. G. Garland and S. J. Hartfall. The Littlewood Prize in Anatomy was awarded to P. R. Allison.

ROYAL COLLEGE OF SURGEONS OF ENGLAND.

Primary Fellowship Examination.

THE following forty-nine candidates have been approved at the first examination for the Fellowship:

V. M. Albuquerque, E. F. Barnardo, J. C. Barrett, C. V. Bloom, A. M. Boyd, W. H. Bremner, E. C. B. Butler, W. S. Chapman, B. Chaudhurt, W. W. Craner, J. Crooks, L. Dass, H. I. Deitch, A. D Everett, J. Fitzsimons, P. H. Fox, A. C. Gairdner, J. M. Gibson, Winifred M. Gray, W. P. Greenwood, C. M. Gwillim, K. W. D. Hartley, T. H. Hobbes, F. W. Holdsworth, M. K. Hussain, H. P. Hutchinson, B. G. Johnston, A. L. Kerr, L. E. Le Souël, O. V. Lloyd-Davies, J. S. Loughridge, T. K. S. Lyle, J. McFadzean, G. K. McKee, G. H. Morley, Eileen S. Morris, M. G. Nimatallah, M. V. P. Peiris, A. S Philps, R. Purvis, R. S. Pyrah, L. A. Richardson, W. M. Robb, G. L. Robinson, E. M. Sharples, H. T. Simmons, J. F. Simpson, V. C. Thompson, J. M. Yoffey.

CONJOINT BOARD IN IRELAND.

THE following candidates have been approved at the examinations indicated:

FINAL EXAMINATION.—D. P. P. Barry, F. A. Carolher, J. J. Lee, P. H. M. McEntee, W. Monnelly, Patricia O'Kane, D. L. Trant, T. Walshe.

DIPLOMA IN PSYCHOLOGICAL MEDICINE.—*Part I*: Dr B. F. Honan.

PRIMARY FELLOWSHIP EXAMINATION.—W. C. Somerville-Large.

FINAL FELLOWSHIP EXAMINATION.—I. J. Fraser, Mary G. Hogan, A. S. ff. O'Carroll.

Winter Session, 1925-1926, and Summer Session, 1926.—The following prizes have been awarded in the later subjects of the curriculum:—Forensic Medicine: Second prize and certificate, Miss D. F. Weir and P. F. Murray. Materia Medica: First prize and medal, A. J. Devlin. Pathology: First prize and medal, A. J. Devlin; second prize and certificate, W. G. Greene. Operative Surgery: Gold medal, P. O'Neill; silver medal, P. O'Callaghan.

Obituary.

JOSEPH EBENEZER ADAMS, M.S., F.R.C.S.,

Surgeon to St. Thomas's Hospital and to the East London Hospital for Children.

WE greatly regret to record the death of Mr. Joseph Adams, which took place on Tuesday, December 21st, 1926. He was the fifth son of the late William Adams, and was born on February 7th, 1878. On leaving the City of London School he gained the entrance scholarship at St. Thomas's Hospital. He had a distinguished career as a student, taking several prizes, and qualified with the M.R.C.S., L.R.C.P. of the English Conjoint Board in 1902. After serving as house-surgeon at St. Thomas's he graduated M.B., B.S.Lond. in 1904, and obtained the Fellowship of the Royal College of Surgeons; in that year too he gained the Beaney Scholarship in surgical pathology. From 1905 until 1909 Adams held the posts of surgical registrar and resident assistant surgeon at St. Thomas's, and was shortly after elected assistant surgeon to the East London Hospital for Children, Shadwell. He became much attached to Shadwell, and retained his position on the active staff until his death, when he was senior surgeon to that institution. In 1911 he obtained the M.S.Lond. degree, and two years later was elected assistant surgeon to St. Thomas's Hospital, being promoted full surgeon in 1923.

In 1913 he was elected Hunterian Professor at the Royal College of Surgeons of England, taking as his subject peritoneal adhesions. This lecture incorporated the result of a great deal of experimental work, for at this early stage of his career he was already taking a deep interest in the purely scientific side of his profession, and until his death he was occupied with research chiefly in relation to abdominal diseases. His experimental work was always carried out with thoroughness and the characteristic attention to detail which stamped everything he did. The results of some of these investigations were used as the basis of a second Hunterian Lecture, which he gave early last year, on the surgery of the jejunum (BRITISH MEDICAL JOURNAL, April 10th, 1926). Shortly before the war he wrote a book on acute abdominal diseases, with the collaboration of Dr. M. A. Cassidy, which more recently he himself revised and enlarged. Although chiefly interested in abdominal work he took an active interest in many other phases of surgery. Adams was generally to be seen at surgical meetings, whether of the Association of Surgeons, of which body he was an original member, the Surgical Section of the Royal Society of Medicine, or other sections. When he spoke, he spoke clearly, concisely, and to the point. He was a great reader and contributed a number of carefully written articles to the medical journals, among which may be mentioned his address on the mortality of appendicitis, published in these columns on April 18th, 1925. His operative work was characteristic of that same care and deliberation which was so much a part of his personality. He was enthusastic about teaching at St. Thomas's, and being a clear thinker himself he presented his subject in that logical way which makes for good teaching.

Adams never shirked his hospital work. He was a man of character with high ideals, and he considered that the training of his house-surgeons and his dressers was a duty not to be lightly undertaken. He often carried on when suffering severe physical discomfort. For years he was handicapped by a disability the cause of which—namely, a congenital diaphragmatic hernia—was not made fully clear until after his death. In 1916, whilst serving as a Captain R.A.M.C.T. on the *à la suite* staff of No. 5 General Hospital (St. Thomas's) and at King George's an exacerbation of symptoms prevented him from serving oversea. This is known to his intimate friends to have been a very real grief to him, but his reserved nature made him shrink from any discussion of his disability. All through his life absolute straight dealing and integrity were the dominating features of his character. In the early days when he was resident assistant surgeon at St. Thomas's he was looked up to and trusted by College House. It would have been impossible for Adams to do a mean or crooked action. He was generous both in his thoughts and actions, a characteristic which was never paraded, for being a sensitive and reserved man he sometimes cloaked his real feelings under a veil of sarcasm. Although, as a student, he played cricket for the hospital, and later took to golf, what he liked best was to get away quietly to the country with his wife. For the last few years he had a cottage near Penshurst in Kent, and nothing gave him greater pleasure than to get his friends and his students down there with him. Everybody had to garden, and he was the keenest gardener of all.

His tragic death at the early age of 48 is a real loss to the profession, to the hospitals at which he worked, and to his friends.

JOSEPH E. ADAMS, M.S., F.R.C.S.

The death of Professor KARL JOSEPH EBERTH in his 91st year, on December 2nd, at Halensee, near Berlin, where he was living in retirement, removes from the world one of the pioneers of bacteriology and the Nestor of German pathology. Born on September 21st, 1835, he studied under Kölliker, Virchow, Leydig, and Heinrich Müller at Würzburg, where he wrote his doctor's thesis on *Trichocephalus dispar* in 1859. In 1865 he was appointed professor of pathological anatomy at Zürich, and nine years later professor of histology at the veterinary school in that city, where he remained until 1881. He was then called to the chair of histology and comparative anatomy at Halle, where in 1895 he was made professor of pathological anatomy and director of the pathological institute, and remained until his retirement. His discovery of the typhoid bacillus, for which he is best known, was described by him in *Virchow's Archiv* in 1880 and 1881. His other bacteriological writings include papers on pseudo-tuberculosis in the guinea-pig, coccal infection in the parrot, and contagious diseases in rodents. Eberth's activities, however, were not confined to bacteriology. In addition to important investigations on thrombosis, carried out for several years in conjunction with Schimmelbusch, he pub-

lished studies on the histological structure of the liver, regeneration of epithelium, amyloid disease, leukaemia, and growth of bone. Eberth was a master of microscopical technique, and was therefore admirably fitted for editing Friedländer's work on this subject. He was also the editor of the *Fortschritte der Medizin* and other medical journals for some years.

Dr. HUGH CAMPBELL ROSS died on December 14th, 1926, of pneumonia on his way to this country from India, and was buried at sea. He was born in 1875, a son of General Sir Campbell Ross, K.C.B., and the younger brother of Sir Ronald Ross. He received his medical education at St. Thomas's Hospital, and took the diplomas of M.R.C.S. and L.R.C.P. in 1898. He served in the South African war as a civil surgeon, receiving the Queen's medal and five clasps, and also, from 1902 to 1906, in the Royal Navy. From 1906 to 1908 he was medical officer in the Public Health Department, Egypt, and was specially engaged in the control of mosquitos. In 1908 he resumed work at the Royal Southern Hospital and the School of Tropical Medicine, Liverpool, and in 1910 was appointed director of the research fund established by the late Mr. McFadden, a broad-minded and generous American. His researches were directed mainly to the nature and prevention of cancer, upon which he published a number of papers. He also contributed a chapter on Egypt to his brother's book on the prevention of malaria. In 1913 a paper by him on gasworks pitch industries and cancer was published in our columns.

Dr. JOHN JOSEPH MACDONNELL, who died in the first week of December, 1926, received his medical education at Queen's College, Galway, and obtained the diplomas L.R.C.P. and L.R.C.S.Ed. in 1879. He practised at Letterfrack, co. Galway, for forty-three years, and was in charge of the Renvyle Dispensary District. He was for many years a member of the South Connaught Division of the British Medical Association, and was held in much respect by his colleagues in the district. His elder brother was the late Lord MacDonnell, at one time member of the Council of India, and for six years Under Secretary of State in Ireland. Another brother was the late Dr. Mark MacDonnell, formerly M.P. for Queen's County.

Medical News.

LADIES and friends of medical men are invited to the meeting of the Post-Graduate Hostel at the Imperial Hotel, Russell Square, W.C., on Tuesday, January 4th, when Dr. Charles Goddard will deliver, at 9 p.m., an address entitled "Lord Lister, by One who knew him."

THE Friday evening discourses at the Royal Institution of Great Britain, which are given at 9 o'clock, will be resumed on January 21st, 1927, when Sir William Bragg will speak on Tyndall's experiments on magne-crystallic action. On January 28th Dr. E. P. Cathcart, F.R.S., professor of chemical physiology in the University of Glasgow, will discuss the physique of women employed in industry.

THE Hunterian Lecture will be delivered before the Hunterian Society of London at the Mansion House at 9 p.m. on Monday, January 17th, by Dr. J. M. T. Finney of Baltimore, who has chosen as his subject "The influence of John Hunter on American surgery."

THE Nobel prize for chemistry for 1926 has been awarded to the Swedish professor Dr. Svedberg. Up to the present the recipients of the Nobel prizes for physics, literature, chemistry, medicine, and peace are ranged in the following order: German 28, French 21, British 15, Swedish 9, Swiss 8, American 7, Dutch 6, Danish 6, Belgian 5, Austrian 5, Norwegian 4, Italian 4, Spanish 2, Polish 2, Canadian 2, Russian 1, Indian 1.

THE Joint Nursing and Midwives' Council of Northern Ireland, being about to revise its list of examiners, invites applications from registered medical practitioners, including women (resident in Northern Ireland), who would be willing to act. Particulars can be obtained from the Registrar, 118, Great Victoria Street, Belfast, to whom application should be sent not later than January 15th.

MAJOR R. W. H. JACKSON, B.A., M.D., D.P.H., Assistant Controller British Red Cross Society (Carnarvonshire), has been elected a member of the Carnarvonshire Territorial Association.

THE Ministry of Health has issued a circular to public health authorities prescribing the character of the report a medical officer of health should present for 1926. It should be an ordinary report, and not the full survey report asked for last year. The Ministry laments that some of these full reports have not yet been received.

THE next French Congress of Legal Medicine will be held at Lyons in July, 1927, under the presidency of Professor Etienne Martin, when a bust of the late Professor Lacassagne will be unveiled and the following subjects discussed: (1) Pathological thieving, introduced by MM. Ravlart and Nayrac of Lille; (2) accidents caused by electric currents, introduced by M. Naville of Geneva; (3) wounds caused by projectiles, introduced by M. Piédelièvre of Paris.

INTERNATIONAL post-graduate courses will be held in Berlin during March and April, and will include general medicine, diseases of the kidney and the circulatory system, and radiology. A course in diagnosis and therapeutics will occupy the first fortnight in April, and opportunity will be provided for clinical and laboratory work in Berlin hospitals. Further information may be obtained from the Office of the International Post-Graduate Courses, Kaiserin Friedrich-Haus, Luisenplatz 2-4, Berlin N.W.6.

THE Ministry of Health has issued a circular (No. 750) to Poor Law authorities in England and Wales with reference to the provision of surgical dressings. Arrangements have been made with the director of the Manchester testing house to report upon samples of dressings sent to him by boards of guardians at specially reduced fees. It is suggested that before boards enter into any fresh contract for the supply of surgical dressings a stipulation should be made that the goods should be of the standard specified in the *British Pharmaceutical Codex, 1923*, as amended. With a view to economy it is recommended that bandages of three or four yards in length should replace to some extent the usual six yards standard.

VISCOUNT KNUTSFORD, who presided at the annual meeting of the British Charities Association, reported that the grants made by the association during the year amounted to £76,700, an increase, as compared with the previous year, of £46,000. A distribution to the British hospitals beyond the London area amounting to £45,000, a grant to King Edward's Hospital Fund for London of £20,000, and to the League of Mercy of £5,000 constituted the bulk of this sum.

Letters, Notes, and Answers.

All communications in regard to editorial business should be addressed to ***The EDITOR, British Medical Journal, British Medical Association House, Tavistock Square, W.C.1.***

ORIGINAL ARTICLES and LETTERS forwarded for publication are understood to be offered to the BRITISH MEDICAL JOURNAL alone unless the contrary be stated. Correspondents who wish notice to be taken of their communications should authenticate them with their names, not necessarily for publication.

Authors desiring REPRINTS of their articles published in the BRITISH MEDICAL JOURNAL must communicate with the Financial Secretary and Business Manager, British Medical Association House, Tavistock Square, W.C.1, on receipt of proofs.

All communications with reference to ADVERTISEMENTS, as well as orders for copies of the JOURNAL, should be addressed to the Financial Secretary and Business Manager.

The ***TELEPHONE NUMBERS*** of the British Medical Association and the BRITISH MEDICAL JOURNAL are *MUSEUM 9861, 9862, 9863, 9864* (internal exchange, four lines).

The ***TELEGRAPHIC ADDRESSES*** are:
EDITOR of the BRITISH MEDICAL JOURNAL, *Aitiology Westcent, London.*
FINANCIAL SECRETARY AND BUSINESS MANAGER (Advertisements, etc.), *Articulate Westcent, London.*
MEDICAL SECRETARY, *Mediscera Westcent, London.*

The address of the Irish Office of the British Medical Association is 16, South Frederick Street, Dublin (telegrams: *Bacillus, Dublin*; telephone: 4737 Dublin), and of the Scottish Office, 6, Drumsheugh Gardens, Edinburgh (telegrams: *Associate, Edinburgh*; telephone: 4361 Central).

QUERIES AND ANSWERS.

CHRONIC OBESITY.

DR. G. H. RUTTER (Eastbourne) writes in reply to "W. J. K." (JOURNAL, December 11th, 1926, p. 1151): For the last twenty years I have met no case of chronic obesity (with or without cardiac dropsy) that I have not been able to bring down to the average normal weight by a carefully carried out electric treatment, strictly in accordance with the late Dr. Bergonié's own directions. But, to quote his words to me: "The apparatus must be made strictly in accordance with my own views" and not, as pointed out to me by him at the time, similar to that of any of the makes exhibited at the London exhibitions). "Do you think," he said, "after working for fifteen years in

to perfect my apparatus, I do not know how I think it ought to be made to give the results I made it for? The diet is also most important, and if not carried out strictly on the lines I have stated, the patient stands a grave risk of exchanging the obesity for chronic nephritis." (I may state I have seen more than one such instance where the treatment has not been carried out by a medical man.) About 3½ lb. weight should be lost a week, or a stone a month, and in cases accompanied by dropsy as much as 9 lb. in the first treatment has taken place in some of my patients. One male patient lost as much as 40 lb. in a course of two series of treatments lasting about six weeks each or less. This same patient lost 2 ft. in girth. At the commencement of treatment he could not walk fifty yards, whereas at the end of the treatment he stated he "was not walking less than eight miles a day."

ULTRA-VIOLET LIGHT IN RAYNAUD'S DISEASE.

DR. JUSTINA WILSON (London) writes in reply to Dr. Sidney Matthews: Ultra-violet light has a marked effect on Raynaud's disease, which may be regarded as an expression of vaso-constrictor spasm. The good results of this treatment are due to the indirect action of light, which is carried down to the tissues by the agency of the sympathetic nervous system. Irradiation causes a general hyperæmia and sympathetic hypotonia. Much work has been done on this at Jesionek's clinic at Giessen, and there is definite evidence of the effect of ultra-violet light on the sympathetic nerve ends, which would appear to stand in some close relationship to the basal epithelial cells, where the bulk of these rays is absorbed. I have had very good results in treating this and other conditions in which variations of capillary permeability and vasomotor tone are observed—results which are distinctly superior to any obtained by electrical methods. Treatment consists in general ultra-violet light baths two or three times a week, followed by a shorter and rather intenser treatment to the hands and feet. This, again, should be supplemented by instruction in circulation exercises, consisting of definite muscle contractions and relaxations.

PTYALISM.

DR. H. M. MORRIS (Radiologist, Salford Royal Hospital, Manchester) writes: Dr. W. Erle Farnham (JOURNAL, December 18th, 1926, p. 1205) may find *x* rays skilfully administered of value for this condition. An accidental over-exposure of the salivary glands to the *x* rays often causes dryness of the mouth, due to diminished activity of the glands, and there is no reason why this fact should not be applied therapeutically.

BOILS AND CARBUNCLES.

"R. F.," who resides in Scotland, asks if others have observed a great increase in the number of cases of boils, carbuncles, and septic skin conditions generally. During the past ten weeks or so the number of cases of carbuncles in the neck has been very large indeed; there have also been cases of carbuncles in the arms and many cases of septic skin conditions. Furuncles in the ears are also more common than usual. No one class of the community seems to be specially affected; in no case has glycosuria been found. Does the condition result from lack of proper bodily cleanliness, owing to the diminished supply of hot water during the coal strike, or has it some connexion with the diet?

LETTERS, NOTES, ETC.

THE TOOTH-BRUSH: BOON OR BANE?

MR. A. ANNESLEY GOMES, F.R.C.S., L.D.S. (Burnley), writes in reply to Dr. G. M. MacPhail (BRITISH MEDICAL JOURNAL, December 18th, 1926, p. 1206): The first essential requirement is full appreciation by the individual of oral hygiene. Without this consciousness and co-operation on his part no human device can be satisfactory. A dentist during his daily routine sees ample evidence of the lack of it. Next, there is a knack in the manipulation of a tooth-brush which dentists are endeavouring to teach all who come under their care. A tooth-brush whose bristles are sufficiently apart to enable cleaning and ventilation should be chosen, and when properly manipulated should not injure the gums or teeth. If a denture is crowded or irregular the use of a metal tooth-pick (a non-rust one—for example, silver) also may be necessary. The brush and pick could be sufficiently cleaned for all practical purposes by washing with soap and hot water, preferably under a running tap, and in the intervals should be kept in a ventilated tooth-brush case; as an extra measure a few grains of paraform placed in the case will supply a disinfecting atmosphere inside it. Perchance in the not far distant future we may see the custom grow up of having several tooth-brushes and of using them in rotation, thereby allowing enough time for each to be disinfected in a specially designed case after the daily ablutions. We have an analogy in the box of seven razors for the seven days of the week which some men possess.

DISLOCATION OF OUTER END OF CLAVICLE.

M.B., B.CH.(Cantab.) writes: Mr. A. B. Mitchell's paper in the JOURNAL of December 11th (p. 1097) on suturing a dislocated clavicle has reminded me of my own personal experience, which may be of interest. Some twenty years ago, when playing in the 'Varsity Rugger match, I had the misfortune to be kicked on the right shoulder when falling on the ball to stop a rush. I attempted to continue, but this was so painful that I was forced to stop, and, when examined by several medical men, I was told that I had better go to the nearest hospital, as my right collar-bone was dislocated at the outer end. I received first aid at the West London Hospital. I do not remember the exact treatment, but suture was certainly not performed and my recovery was complete. I put it down to playing tennis in the next term. Some four years later, when I was a medical student, I lost control of my bicycle when descending a steep hill, and was thrown on my right side against a stone wall. My right shoulder was much bruised and I rather thought something had gone; I was advised to lie flat in bed with the arm in a sling or lightly bandaged. Two or three days after, when in bed, I was unable to prevent a sneeze, and immediately I experienced a sharp pain, and on placing my fingers over the clavicle could quite distinctly feel the jagged fracture. This was reduced and kept in position by the usual bandaging. I again made an uninterrupted recovery, and never have I felt any unpleasantness from either the dislocation or the fracture, nor did it deter me from playing Rugger and tennis, and indulging in rock climbing and mountaineering.

A CONTRACEPTIVE PESSARY.

DR. J. A. DAVIDSON (Hanwell, W.) writes that since his note on a contraceptive pessary was published in the JOURNAL of August 9th, 1924 (p. 258) its composition has been modified; it now consists of magnesium sulphate, with 1 per cent. of lactic acid and 0.5 per cent. of quinine bisulphate. For use in cases of chronic vaginitis the makers (Tocker, Lindly House, Gunnersbury Lane, W.3) now put them up with protargol 2 per cent. or ichthyol 5 per cent., in place of lactic acid and quinine. Their advantage over other pessaries is their slow solubility, which keeps the active agent in contact with the mucosa for many hours.

LIGHT TREATMENT FOR LOSS OF HAIR.

IN the notice of Dr. Nagelschmidt's book on the light treatment for the loss of hair (JOURNAL, December 4th, 1926, p. 1058) the lamp used should have been described as the Hanovia quartz lamp. An English translation of his book has now been published by the Sollux Publishing Company, Slough, under the title of *Loss of Hair and its Treatment by Light*.

RESEARCH IN GENERAL PRACTICE.

DR. EDWARD B. FFENNELL (Clevedon, Somerset) writes: Might I protest indignantly against the statement made by Dr. Vincent P. Norman (JOURNAL, December 18th, 1926, p. 1197) about the teaching of midwifery in hospitals? I became L.M. of the Rotunda Hospital, Dublin, in 1887, and have never ceased to congratulate myself on having been taught there, and consequently having been able to attend quite an average number of confinements for many years.

PROPOSED NEW MOTOR LEGISLATION.

IN view of the new legislation which is
the law relating to motor vehicles, t
has issued a set of questions to its
motorists will probably find little difficulty in answering nearly all of them in the affirmative. The doctor, notwithstanding his continuous use of his car, may well regard a tax on petrol as fairer than the present tax on horse-power. No motorist can object to be given three days in which to produce a licence which he has inadvertently left at home. The proposal that the paid driver and not the employer (as foreshadowed under the new Act) should be responsible for the renewal of the driver's licence will, if adopted, be a pleasant relief. The introduction of penalties for "joy riding" will give some satisfaction to those whose cars are damaged during unauthorized use. The only questions on which there may be some doubts are those in which the abolition of speed limits is proposed. It is quite true that the present speed limits are grotesque; it is also true that strict enforcement of these limits is practically a thing of the past. Nevertheless they give some sort of
help to keep prosecutions for driving
at a minimum. If speed limits are
be liable to be charged by a policeman, untrained generally in motoring, with dangerous driving. No motorist will be safe unless the police are given some sort of standard by which to judge danger. The off-side rule, which has often been advocated in our columns, would form a useful foundation for the policeman's knowledge.

OSTEO-ARTHRITIS OF THE HIP-JOINT: A CORRECTION.

DR. H. WARREN CROWE (Harrogate) desires to correct Dr. W. J. Midelton's statement (JOURNAL, December 11th, 1926, p. 1152) that—in his (Dr. Crowe's) cases—non-specific toxin was used. "There is no justification," Dr. Crowe writes, "in my paper for the assumption that my treatment was not specific. In fact, the reverse is suggested. My words were as follows: 'Beyond saying that the chief vaccine used was made from streptococci obtained from foci of infection, no further details are here given,'" etc. I have always disliked the unscientific and reactionary principles which seem to underlie non-specific protein therapy.

VACANCIES.

NOTIFICATIONS of offices vacant in universities, medical colleges, and of vacant resident and other appointments at hospitals, will be found at pages 35, 38, and 39 of our advertisement columns, and advertisements as to partnerships, assistantships, and locumtenencies at pages 36 and 37.

A short summary of vacant posts notified in the advertisement columns appears in the *Supplement* at page 12.

Observations ON THE MATERNAL MORTALITY IN THE MIDWIFERY SERVICE OF THE QUEEN VICTORIA'S JUBILEE INSTITUTE.

BY

JOHN S. FAIRBAIRN, M.A., B.M., B.Ch.Oxon., F.R.C.P., F.R.C.S.,

OBSTETRIC PHYSICIAN TO ST. THOMAS'S HOSPITAL.

ANY information regarding the maternity service of the country is of interest and value, particularly at the present moment, when so much discussion has taken place regarding its shortcomings and the need for its improvement, and a Committee of the British Medical Association has under consideration the causation of puerperal morbidity and mortality.

I am indebted to the council of the Queen Victoria's Jubilee Institute (Q.V.J.I.) for access to its statistics for the last two years and for the results of such of the past twenty years' work as are available. The information placed at my disposal appears to me worthy of a wider publicity and more detailed analysis than that afforded by the annual report of the Institute, embodying as it does the results of the work of the largest midwifery service in the country under a central organization.

A few preliminary observations are necessary to make clear the nature and scope of the work of the Q.V.J.I. and what the figures represent.

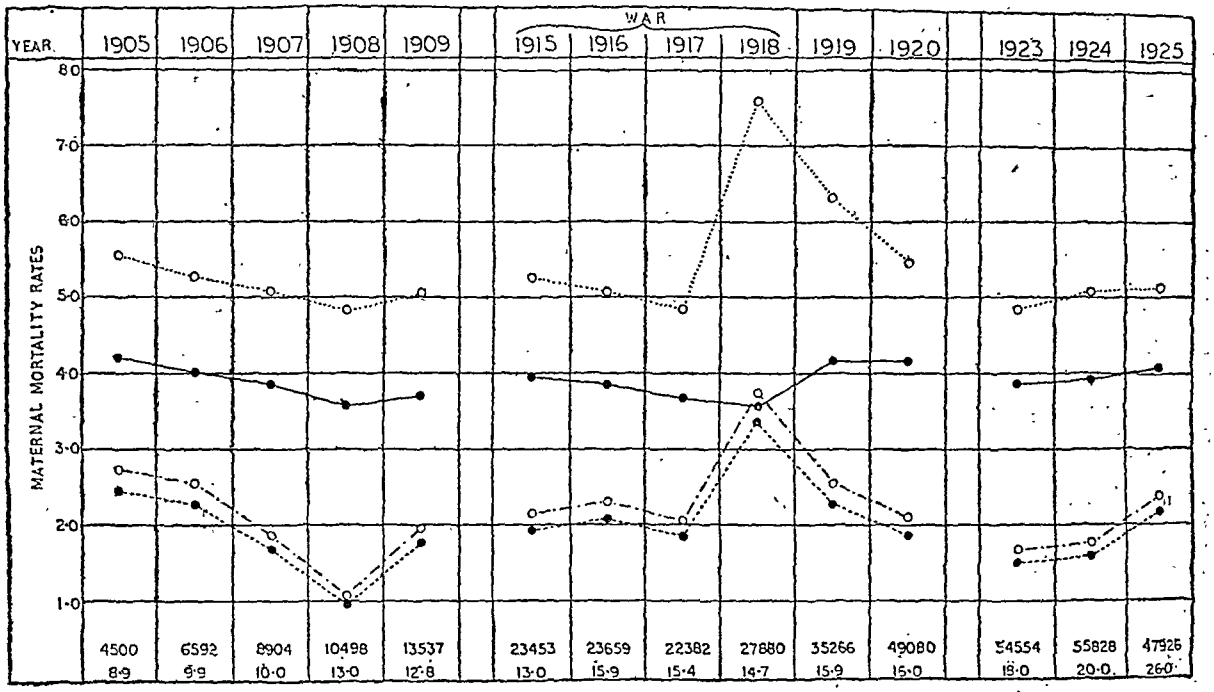
Excepting Essex, Northumberland, and Wilts, practically the whole of England and Wales is covered by the Queen's nurses and the nurse-midwives of the Queen's Institute working through their county nursing associations. For the most part their activities are confined to rural and semi-rural areas, but include also mining (Wales and Durham) and industrialized areas (Lancashire and Yorkshire), and roughly may be taken as representative of the country generally, except London and the large cities and county boroughs. As these latter are the areas with the lowest maternal mortality, and the rural, textile, and mining areas are those with the highest, the districts served are those in which the results would naturally be expected to be worse rather than better than those of the country as a whole. The work is carried on by midwives under the supervision of local practitioners, without the resources and services obtainable in London and other large centres. Even in the small proportion of cases in which patients are transferred to hospital, no real specialist services are available.

The returns from the county associations are collected and tabulated at the headquarters of the Q.V.J.I. and arranged into two categories: first, those in which the attendant acts as maternity nurse for the doctor; and second, the cases in which she has been engaged to attend as a midwife and only calls in the doctor in accordance with the rules of the Central Midwives Board. The two categories of maternity nurse and midwife are differentiated on the basis of practice and custom. Whenever a midwife is engaged to attend the labour or is the first to be called in by the patient in an emergency, the case goes into the second group, even if the doctor has continued in attendance. Save in sudden and fatal emergencies, all patients whose death falls in this group were seen and treated by the doctor. The cases in the maternity nurse category are not included in this review, the midwives not being subject to the rules of the Central Midwives Board if the doctor arrives to take charge, and, the case being the doctor's, the necessary information is not available.

In order to make comparison of these figures with the Registrar-General's returns more exact, certain adjustments must be made, as the basis of computation in the two is not the same.

The Registrar-General records the number of maternal deaths for every 1,000 live-born infants whose births are registered in that year, whereas the figures under consideration are the maternal deaths in 1,000 deliveries. The stillbirth rate (about 3.3 per cent.) would increase the Q.V.J.I. figures to that extent; on the other hand, twin live births count as two in the national returns and as one delivery in these figures, so, taking the average number of twin births as 1.2 per cent., and allowing 1 per cent. as the figure for twin live births, an addition of 2.3 per cent. to the Q.V.J.I. figures would be a correct adjustment.

The great difference, and the one most calling for adjustment, is that the Registrar-General includes in his mortality figures deaths in pregnancy due to abortion, ectopic gestation, pernicious vomiting, and such-like, none of which fall within the sphere of the midwife. The mortality due to pregnancy is not represented in these figures, save for a certain proportion of the cases of ante-partum haemorrhage that come into that heading (Code number 143). Even though it weights the scales slightly against the figures under consideration, the plan will be adopted of calculating the percentage to be added to the Q.V.J.I. figures on the basis of the average percentage of these pregnancy deaths in the Registrar-General's returns for the five years 1920-24.



Finally, the figures taken for comparison are not those usually quoted for the mortality due to child-bearing, in which the "associated deaths" are excluded, but those including the deaths returned as "either caused by or associated with pregnancy and childbirth," because these "associated" deaths are included in the Q.V.J.I. figures, and, indeed, form there a larger percentage of the total than in the Registrar-General's figures, probably from faulty returns. The allowance to be added to the Q.V.J.I. figures will be about 11 per cent., made up of over 8 per cent. for deaths in pregnancy and over 2 per cent. for stillbirths less live twin births. A line showing the "adjusted" mortality rate (dot and dash line) to compare with the national rate (dotted line) is included in the chart (p. 48). The uninterrupted line shows the maternal mortality line, usually quoted (that is, excluding "associated" deaths), and the line of short dashes the unadjusted rate of the Q.V.J.I. puerperal and associated deaths per 1,000 labours. The calculation of these adjustments and the preparation of the chart from the figures supplied by the Q.V.J.I. has been undertaken for me by Dr. Matthew Young of the Statistical Department of the Medical Research Council, for whose assistance in the matter I am greatly indebted.

That these are to some extent a selected group of cases is not questioned. The outstanding impression left after a study of these statistics is that what selection is made is of the most haphazard order and appears to be largely left to the midwife. It is certainly determined more by the social and economic conditions than the obstetric or medical necessities of the individual patient. The chief lesson to be learnt is that if a mortality can be obtained well below that of the nation generally without any adequate system of ante-natal observation and selection of cases, the already low death rate could be made lower still by an organized system of ante-natal observation and selection of cases together with proper provision for cases in which complication was anticipated or had arisen.

The increasingly prominent position occupied by the nurses and nurse-midwives of the Q.V.J.I. in the country's maternity service is shown by the total number of cases in which they have taken part, being multiplied almost tenfold within twenty years—from 8,322 in 1905 to a maximum of 80,147 in 1924, with a drop to 73,011 in 1925. The proportion of cases attended in the two capacities works out roughly at two-thirds as midwife and one-third as maternity nurse. In the first period, covering six years, it is 59 to 41 per cent.; in the second six-year period 67 to 33 per cent.; and in the final three-year period 69 to 31 per cent.

Throughout the years for which figures are available the mortality in the midwives' cases is under half that of the general rate for England and Wales, and its variations diverge little from those of the Registrar-General's returns. The consistently lower mortality rate may be accepted as demonstrating the value of the services of a well trained corps of midwives in this country and as bearing out the evidence of the lower maternal mortality in those European countries, such as Holland, Italy, and the Scandinavian nations, which have had for generations a well organized midwifery service.

Chart Showing Comparison of Maternal Mortality Rates (Registrar-General) in England and Wales and in Cases Attended by the Queen Victoria's Jubilee Institute Midwives.

Dotted line with open circles=rate for England and Wales including "associated" deaths per 1,000 live births. Black line with black circles=rate for England and Wales excluding "associated" deaths per 1,000 live births. Dot and dash line with open circles=rates of Q.V.J.I. midwives per 1,000 deliveries adjusted for comparison with R.-G.'s returns, including "associated" deaths per 1,000 live births. Dotted line with black circles=rate per 1,000 deliveries in cases attended by Q.V.J.I. nurses acting as midwives. The figures below show the number of cases attended by Q.V.J.I. nurses acting as midwives for each year, with the percentage of cases in which medical aid was summoned. The two lines affording the most accurate comparison are the two with open circles, the dotted line and the dot and dash line giving the "adjusted" rate, Q.V.J.I.

The figures on the chart showing for each year the percentage of cases in which a practitioner is summoned to her aid by the midwife are worthy of note. Although a gradual increase in the proportion of medical aid notices is evident up to the years immediately after the war, it is in the records of the last three years that it becomes specially marked. Certainly the figures of the last year (1925), when medical aid was summoned in over a quarter of the cases attended, suggest a lack of experience and a failure to take responsibility on the part of the midwife. Doubtless there are many factors contributing to this increased calling on medical services. The rules of the Central Midwives Board involve the calling in of a practitioner for many other conditions than difficulties in labour, and the general tightening up of the administration of the Midwives Act by the local authorities throughout the country has resulted in medical aid notices being sent as a precautionary measure for many conditions—for example, in the case of the child, for "any inflammation of, or discharge from, the eyes, however slight." Also the making of the practitioner's fee payable by the local authority in the Act of 1918 has rendered it easier for the midwife to obtain such assistance.

In order to find the reason for the calling in of medical aid, special inquiries were made from the Q.V.J.I. midwives in 1924 and 1925, to ascertain the proportion of calls for the mother during labour. In the former year 7,601 out of 11,307 calls (or 67 per cent.) were on account of complication or delay in labour, and the corresponding figures for 1925 were 8,620 calls out of 12,700 (or 68 per cent.). Over the whole number of cases attended the percentages for the two years are respectively 13 and 17.9 in which calls were made for difficulty or delay in labour—obviously a poor showing so far as the primary objective in midwifery is concerned, that of securing natural parturition. As the figures for 1924 showed that in 48 per cent. of the cases in which aid was sought for the mother in labour delivery was effected by the forceps, they are disappointing as regards the success both of the midwife and the practitioner summoned to her aid in obtaining natural delivery and avoiding interference. They indicate nervousness and impatience on the part of the midwife, and suggest also inefficient training in the use of opium or other sedative to avoid fatigue of the mother. If sedative treatment was more generally adopted by the midwife, and medical aid summoned only after it had been tried and failed, the proportion of natural deliveries would be greatly increased. The present-day midwife certainly appears to have become less self-reliant than her shorter-trained predecessor, and to be more readily infected with the impatience and anxiety of patients and their relatives. The steadily increasing rate of sending for the doctor shows no corresponding improvement in the maternal mortality rate.

The stillbirth rate is nearly constant: for the last three years it was 3.3, 3.5, and 3.1 per cent.

In the last two years an effort has been made to obtain from the midwives the causes of death as certified by the practitioners called to their aid, and although not authoritative, they are probably as nearly correct as the certificates themselves. They have been classified as follows:

Causes of Death.	1924.	1925.	Total.	Per Cent.
Puerperal sepsis	12	28	40	21.2
Embolism and thrombosis	14	10	24	12.7
Haemorrhage (including placental complications)	17	19	36	19.0
Labour complications and shock...	5	11	16	8.5
Eclampsia	8	10	18	9.5
Other diseases associated with childbirth ...	31	24	55	29.1
Total	87	102	189	100.0

The number of cases attended was 55,828 in 1924, 47,926 in 1925—a total of 103,754.

A brief analysis of the causes of death will serve to give an impression of the difficult conditions under which both practitioners and midwives work, and to emphasize the importance of further organization and co-operation between them.

Of the 40 cases of death from puerperal sepsis, 15 patients were removed to hospital. In all except 9 there is no reference made to abnormality in the labour; in 2 it is noted that no vaginal examination was made, and in one that there was only one examination. There were 4 cases of delivery by the forceps (one with complete rupture of the perineum and sloughing), 4 cases of manual removal of the placenta (in one of which the child was born before the arrival of the midwife), and one of placenta praevia. Two cases occurred at the same time in the practice of one midwife.

Of the 24 deaths ascribed to *embolism and thrombosis*, 7 patients died on the day of delivery; one patient died in hospital, and two inquests were held, but most of the others appear to have been ill in some way and under the doctor. The chief complications noted were adherent placenta in 4 cases, delivery by the forceps and post-partum haemorrhage in 2 cases, forceps in one, and phlegmasia in one.

Of the 36 deaths from haemorrhage, 23 were termed ante-partum haemorrhage and 6 post-partum haemorrhage. There are included also 6 cases described as adherent placenta in which manual removal was performed, and one of inversion of the uterus with haemorrhage. The holding of an inquest is only mentioned once, so that in the other cases presumably medical aid was obtained in time for a death certificate to be given. Five of the ante-partum haemorrhage cases were at once removed to hospital; in 2 of these it is stated that the midwife was called in in emergency (that is, not engaged beforehand). Though details of treatment are not, as a rule, mentioned, delivery is stated to have been effected by the forceps in 4 cases, 2 of which were followed by post-partum haemorrhage; in another death is ascribed to heart failure, and in the remaining case to collapse twenty minutes after delivery. These instances which do happen to be noted are enough to show that the danger of rapid delivery in ante-partum haemorrhage is not generally appreciated, and that the breaking of the fundamental principle of encouraging expulsion by the natural powers rather than hastening delivery by artificial methods is bound to be costly.

Among the deaths from post-partum haemorrhage is one in which birth had taken place before the midwife's arrival, the patient being found collapsed on the floor. In one case, in which the doctor expressed the placenta, the failure to control the bleeding was ascribed to haemophilia, and in another, in which there was an adherent placenta, a large goitre was thought to be a complicating factor. In another case the patient was seen and treated by the doctor within half an hour and survived for a fortnight, but the primary cause of death was certified as post-partum haemorrhage. Of the 6 deaths returned as following manual removal of the placenta, one patient was sent to hospital, where she died the following day, one was described as having collapsed immediately, another as dying from post-partum haemorrhage in sixteen minutes, and in another exhaustion and starvation were mentioned as contributory factors. No details are available as to the others, save that in all cases the operation was performed by the practitioner called in. It may be worth while to draw attention to the prominent place occupied by this dangerous operation throughout these mortality statistics. The case of inversion occurred in the premature labour of a woman ill with influenza, the patient dying before the arrival of medical assistance. As post-partum haemorrhage is an emergency in which the midwife may have to rely on her own resources, the evidence of these figures does not seem to show a risk above the average.

The deaths from ante-partum haemorrhage emphasize the importance of looking on all bleeding in the second half of pregnancy as a warning of more serious trouble ahead, and the need for hospital facilities for the observation and treatment of such cases. Many of the ante-partum haemorrhage cases should not have been left in the charge of a midwife. In time the education of the mothers in understanding the significance of losses of blood during pregnancy and in reporting their occurrence immediately should make it easier to arrange for special provision being made.

The 16 deaths under complications of labour and shock were mostly due to malpresentations, misfits, monsters, and such-like, some of which ought to have been detected before labour; 5 were admitted to hospital. There were 2 cases of contracted pelvis; one patient died after Caesarean section in hospital, and the other shortly after craniotomy had been performed after failure to deliver with the forceps. A 7-para died in the infirmary after a "complicated breech delivery," and another in a county hospital into which she was sent as a brow presentation. There were two cases of monsters, in both of which the patients were sent into hospital only after failure to deliver them at home. There was one case of hydrocephalus, one of foetal ascites, and another in which the foetal thorax was opened before delivery could be effected; there were 2 cases of fibroids complicating pregnancy, and others in which death resulted shortly after operative delivery. In one case, in which the child was born before a midwife arrived, death is ascribed to syncope after a precipitate labour.

The 18 deaths due to eclampsia are instructive; among them 6 were emergencies, and in 3 no definite particulars were given. In the remaining 9, ante-natal supervision of some kind was given. Labour was induced in one; of 3 patients it is stated that "she could not supply a specimen of urine," that "she refused to supply one," and that "the urine was to be tested next visit, but the convulsions (at the seventh month) began before it was done." Of the 5 others the urine is stated to have been tested and found free from albumin. In one of these cases a fit occurred eight hours after a normal labour and the patient was transferred to hospital, where she died the following day. These cases indicate clearly the need for improvement both in a more frequent examination of the urine and in the education of the mothers in the necessity for supervision during pregnancy.

In the miscellaneous group of complicating conditions the largest number of deaths (33 out of 55) are said to have been certified as influenza, pneumonia, or bronchitis, and the next largest (11) to cardiac disease, sometimes with bronchitis; 3 deaths were ascribed to cerebral haemorrhage, 2 to tuberculosis, one to measles and congestion of the lungs. An inquest was held on one patient who previously suffered from influenza, and the verdict was "heart failure," and 6 patients died after transference to hospital. A striking point in this group is that many of the women were under medical care beforehand, but the confinement was left to the midwife. For the most part they should not have been midwives' cases.

On the whole these figures show an exceedingly creditable record of what can be done by the partnership of doctor and midwife, but could be greatly improved if paragraph 41 in the Scottish Departmental Committee's Report on Puerperal Morbidity and Mortality was more fully acted upon. It is there stated:

> "In virtue of the long and costly training and the late age at which professional activity begins, the medical practitioner is an expensive social instrument which it is no economy to use for work that may be performed more simply. There is social confusion when doctor and midwife have to be treated as competitors; they should be considered not as rival to each other, but as complementary."

It is clear that a material proportion of the maternal deaths, and inferentially much disability among mothers who recovered, might be avoided by a better distribution of such services as are at present available by which the medical side should give more time to the supervision of the pregnant woman, and the allocation of the duty of attending labours in accordance with the probable obstetrical requirements of the patient, leaving, so far as can be foreseen, the simpler and normal cases to the less highly trained midwife. The employment of the more "expensive social instrument" for attendance on normal parturition is not only extravagant, but tends to a lessening of the proportion of natural and unassisted deliveries, for which a price has to be paid when the national mortality account is rendered. The increasing rate of summoning medical aid for delay in labour shows that one of the outstanding problems of the present day is that of how to attract the best and most experienced midwives to this work. It is

too big a problem to open here, but it is undoubted that a mere fraction of the best trained women will face the responsibility and strain of practice with its poor prospects of advancement and poor economic return.

Good as is the work of these midwives and of the practitioners who help them, the difficulties of both are much greater than need be, and if better co-operation between the two and better provision for hospital assistance could be organized, there would be a great saving of maternal lives.

It may be worth while to take as an example of what might be arrived at throughout the country the figures of an institution which has succeeded better than any other (to my knowledge) in reaching the highest standard of obstetric practice—the East End Mothers' Lying-in Home. Though a self-contained unit with both a district and hospital practice, it works on the same system as the Queen's midwifery service—that is, the ordinary work is carried on by midwives, and the ante-natal supervision and the rendering of medical aid when called for by the midwives are in the hands of a local practitioner, who thereby has gained special experience. Its results are obtained among its own patients; it neither sends elsewhere its complicated midwifery nor takes difficult midwifery from outside its own patients, so that its work in that way differs from the ordinary maternity hospital.

In the past four years, in 8,943 cases it has a maternal mortality of 0.67 per 1,000 deliveries, and a forceps rate of only 2.38 per cent. In other words, it has one death for every 1,500 deliveries, instead of one for every 250 live children born in the country as a whole, and succeeds in obtaining physiological parturition better than the Queen's midwives, as is indicated by a forceps rate of 2.38 instead of 6.4 per cent. As the later figures for the Queen's service show, the tendency there is rather away from than towards the securing of natural function in labour.

This isolated instance of an institution working on the same lines, but with particular advantages in having experienced but not specialist medical supervision, a highly trained midwife staff, a hospital for its difficult cases, and a close co-ordination of all its services, gives an indication of what might be done in reducing maternal mortality and disability in childbed throughout the country, and in the Q.V.J.I. midwifery service in particular. The problem is that of adapting the conditions of a self-contained unit to the varying circumstances of rural, urban, and industrial areas, with scattered populations, differing personnel, and inadequate resources, and surely it can be solved in part if impossible of complete solution.

This analysis encourages hope of a reduction in the maternal mortality. If the results shown by the Q.V.J.I. midwives with the help of local practitioners obtained throughout the country, the maternal mortality would be more than halved, and might even be greatly improved on that by better team work between midwives, practitioners, and maternity hospitals. These figures lend support to those who contend that a country's maternity service is best built on the foundation of a service of midwives with medical help in difficult cases.

A CASE OF THYRO-PITUITARY ENDOCRINOPATHY.

BY

C. WORSTER-DROUGHT, M.A., M.D.CAMB., M.R.C.P.,

LECTURER IN NEUROLOGY, BETHLEM ROYAL HOSPITAL; PHYSICIAN, WEST END HOSPITAL FOR NERVOUS DISEASES, ETC.

THE following case of Graves's disease, associated with increased function of the anterior lobe of the pituitary gland and diminished function of the posterior lobe, seems worthy of record.

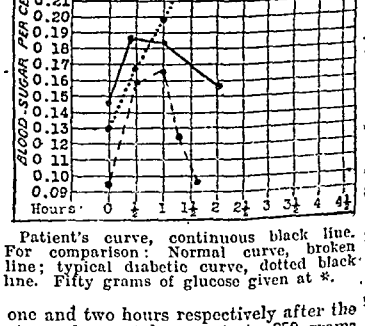
The diagnosis of Graves's disease (hyperthyroidism) rests upon the following symptoms and signs: enlargement of the thyroid gland, exophthalmos, tachycardia (average pulse rate 130), raised blood pressure (140 mm.), pulse pressure (70), fine manual tremors, excessive restlessness, increased psycho-galvanic reflex and basal metabolism, and a positive Goetsch's test.

Hypersecretion of the anterior lobe of the pituitary gland is indicated by the abnormal length of the long bones for the patient's age, the disproportionate size of the hands and feet, and the slightly enlarged sella turcica. Decreased function of the posterior pituitary lobe is suggested by the smooth, soft skin and general hairlessness, absence of pubic and axillary hairs, poorly developed external genitalia, and the relative lymphocytosis.

Description of Case.

The patient is a boy aged 14; he complains of general weakness, breathlessness and palpitation on exertion, nervousness and nocturnal enuresis.

History.—He was a full-time child with normal birth. He is said to have suffered from rickets during infancy, otherwise no previous illness occurred beyond measles and whooping-cough. During the past three years he has grown very rapidly in stature, but at the same time has lost flesh in spite of a good appetite. He is easily exhausted by physical effort, complaining of dyspnœa and palpitation on exertion. Also he has become very restless, unduly nervous, excitable, and inattentive, and suffers from nocturnal enuresis, the latter symptom appearing six years ago. There is nothing noteworthy in the family history. He has two brothers, aged 18 and 12 years, and one sister, aged 17, all of whom are well and show no physical or mental peculiarities.



General Appearance.—He is a tall boy for his age (height 5 ft. 10 in.) and is very thin (weight 7 st. 5½ lb.). In proportion to the trunk, his extremities are long: arms 26½ in.; legs (great trochanter to heel) 37 in.; trunk (vertex of head to tip of coccyx) 30 in. The hands are very large, especially the carpus and metacarpus, also the feet (size 10). All joints appear of disproportionate size, but the jaws are normal. The skin is generally smooth and hairless; there is no pubic or axillary hair; the penis is of infantile type and the testicles are very small. The thyroid gland shows general enlargement.

Circulatory System.—Heart not enlarged: first sound accentuated at the apex with a soft systolic murmur in the pulmonary area as well as over the thyroid. Average pulse rate at rest 130; blood pressure 140 mm. Hg systolic and 70 mm. diastolic. There is considerable vasomotor instability, as shown by an easily and rapidly produced *tache cérébrale* and a tendency to dermatographism. Also, sweating is very free.

Nervous System.—There is some degree of exophthalmos with positive von Graefe, Stellwag, and Kocher's signs. The pupils are dilated and react normally; vision and optic discs normal, fine lingual tremors; speech hurried. All other cranial nerves normal. The muscles generally lack tone and are easily fatigued. Fine rapid tremor of outstretched hands. The arm, knee, and ankle jerks are brisk and equal; abdominal reflexes normal and plantar reflexes flexor. Mentally he is alert and intelligent, but very restless, inattentive, and easily startled.

Biochemical and other Investigations.—Basal metabolism showed a +20 per cent. increase. The psycho-galvanic reflex, tested on the emotometer, was greatly increased. Goetsch's intradermic test for hyperthyroidism (using 0.05 c.cm. of adrenaline solution 1 in 1,000) was immediately and strongly positive. The urine contained no albumin, sugar, or casts. Blood examination showed 5,880,000 red and 6,800 white cells per c.mm., with haemoglobin 98 per cent. (colour index 0.83). Differential blood cell count revealed a relative lymphocytosis — namely, polymorphonuclears 32.5 per cent., small lymphocytes 63 per cent., and large lymphocytes 1.5 per cent. (total lymphocytes 64.5 per cent.); eosinophiles 3 per cent. The resting blood sugar was 0.147 per cent., rising to 0.186 twenty minutes after the patient had ingested 50 grams of glucose, and falling to 0.182 and 0.158 per cent. one and two hours respectively after the glucose (see chart). Alimentary glucose tolerance test: 250 grams of glucose was given by the mouth; one hour later the urine contained a considerable quantity of glucose, but it was absent in specimens taken two and three hours after the meal. X-ray examination showed the sella turcica to be slightly enlarged and the bones of the hands and feet unduly large for the patient's age; the epiphyseal cartilages were also narrower than usual.

Patient's curve, continuous black line. For comparison: Normal curve, broken line; typical diabetic curve, dotted black line. Fifty grams of glucose given at *.

Commentary.

The blood sugar and glucose tolerance investigations in this case are of interest. It is generally agreed that hyperthyroidism and hypersecretion of the anterior pituitary lobe both tend to raise the amount of blood sugar and to decrease sugar tolerance, while, on the other hand, diminished function of the posterior pituitary lobe increases sugar tolerance. It would appear that in this case the combined influence of the thyroid and anterior pituitary lobe on the carbohydrate mechanism has outweighed the effect of diminished posterior pituitary lobe function, with the result that the blood sugar is somewhat raised and glucose tolerance slightly reduced. Similarly with the basal metabolism, the thyroid and anterior pituitary factors tending to increase the rate have to some extent overcome the tendency of the posterior pituitary dysfunction to lower it.

The explanation of the pituitary gland disorder is probably as follows: The increased secretion of the anterior pituitary lobe is of some years' standing and due to a functionally active adenomatous enlargement of this portion of the gland. The effect on skeletal growth is a tendency to "giantism" with mild acromegalic signs (enlarged hands and feet), thus following the rule that hypersecretion of the anterior pituitary lobe occurring before puberty results in giantism with occasional acromegalic features, while hypersecretion developing after puberty leads to true acromegaly. As the pituitary fossa is a closed box roofed over by the diaphragma sellae, and therefore relatively incapable of expansion, the effect of an increase in size of the anterior pituitary lobe is probably to compress the adjacent posterior lobe and thus to interfere with its functional activity. Such an occurrence would account for the indications of posterior lobe deficiency in the case.

I am indebted to Dr. W. E. Carnegie Dickson, pathologist to the West End Hospital for Nervous Diseases, for his kind help in the laboratory investigations of the case; also to my clinical assistant, Dr. D. Davies, and to Dr. W. W. Phillips.

THE UREA CONCENTRATION TEST IN NEPHRITIS AND ITS PROGNOSTIC VALUE.

BY

ROBERT COOPE, B.Sc., M.D., M.R.C.P.,

SENIOR HONORARY ASSISTANT PHYSICIAN, ROYAL SOUTHERN HOSPITAL, LIVERPOOL;

AND

H. WALLACE JONES, M.Sc., M.D., M.R.C.P.,

SENIOR HONORARY ASSISTANT PHYSICIAN, ROYAL INFIRMARY, LIVERPOOL.

THIS paper does not aim at entering into a comparison of the various tests of renal inadequacy, but is an attempt to investigate and follow up a series of cases of nephritis, using the simplest test of renal function (the urea concentration test of Maclean and de Wesselow[1]) and assessing its value for prognosis. When the opportunity occurred to us of investigating a series of renal cases in which, for various reasons, the most consistently useful of the "renal tests" (the non-protein nitrogen content of the blood) had to be omitted, it appeared to us of value to make a judgement upon them, basing it upon the urea concentration test figures, and then to follow up the cases with a view to an estimate of its prognostic value.

We have records of 156 of these cases, which had been previously diagnosed as nephritis on the ground of albuminuria, with or without other symptoms; 27 of them were found, after examination, to be suffering from something other than nephritis, and were therefore discarded.

Unless the patients were too ill to take anything but fluids, a simple hospital diet was given. Daily specimens of urine were examined, and each case was allowed to settle down into hospital régime before the urea concentration test was made.

The technique of the test is well known. The patient empties his bladder and then takes 15 grams of urea dissolved in 100 c.cm. of water. He passes urine at the end of the first hour and at the end of the second hour, and the total quantity passed in each hour is noted. The percentage of urea in each of the specimens is determined. When the amount secreted during an hour does not exceed 120 c.cm. a percentage of less than 2 in that specimen indicates renal inadequacy, while if the amount falls below 1 per cent. a very serious defect is present.

The patient should not take any fluid after 8 p.m. on the evening before the test, and it is advisable to collect the night urine from that time until the bladder is finally emptied just before the dose of urea is given in the morning. The reason for this is that in many of the cases the percentage of urea is higher in this specimen than in any of the test samples, even though there is no diuresis during the test period. This anomaly was present in as many as 31 per cent. of the cases described in this paper. The percentage of urea varied from 0.8 to 2.8 in these particular cases. Whenever it occurred the systolic blood pressure was above 150 mm. of mercury, though no relationship between these two facts is obvious.

Another point of interest concerns the diuretic effect of the urea. If there is any diuresis it usually occurs, as is well known, in the sample of the first hour. Sometimes, however, there is a greater output of urine in the second hour than in the first, while in rare cases diuresis occurs in both first and second hours. In cases of this type the third sample, at the end of the next hour, is of value. After a long experience of the test we believe that it is advisable to make the taking of a sample in the third hour a routine procedure.

We grouped our cases of nephritis into the following categories:

Group I (14 cases). Cases with high blood pressure (over 150 mm. Hg systolic) and efficient kidneys—that is, urea maximum of over 2 per cent.

Group II (35 cases). Cases with defective kidneys, but with only slight or no cardio-vascular changes (blood pressure under 150 mm. systolic).

Group III (73 cases). Cases showing definite renal and cardio-vascular changes.

Group IV (7 cases). Cases where renal inadequacy was associated with renal stone.

The after-histories of the patients in each of these groups were followed for a period of two years after the test had been performed. In Group IV no deaths occurred. The average percentage given by the urea concentration test was 1.3—the lowest being 1.1 and the highest 1.8. In Group I one death only occurred in the two years. This was a case with a blood pressure of 170/90 mm., and a urea maximum of 2.4 per cent.

An analysis of the urea maximum figures in the two main groups, showing renal damage (II and III), is given in Table I.

TABLE I.

Group II, defective kidneys with slight or no vascular changes:	
Above 1.5 per cent.	6 cases
1 to 1.5 per cent.	22 ,,
Below 1 per cent.	9 ,,
Group III, defective kidneys with marked vascular changes:	
Above 1.5 per cent.	24 cases
1 to 1.5 per cent.	37 ,,
Below 1 per cent.	12 ,,

In many of these patients the test was repeated from time to time, and the highest figure is used in the above table.

TABLE II.—*Cases which Died within Two Years (Groups II and III).*

GROUP II (5 cases).

No. of Case.	Blood Pressure.	Urea Concentration Test.	Time Lived.	No. of Case.	Blood Pressure.	Urea Concentration Test.	Time Lived.
	mm.	%			mm.	%	
30	140/110	0.5	1 mth.	118	130/90	0.65	9 mths.
32	140/90	0.6	2 mths.	60	125/85	1.0	10 ,,
142	135/95	0.6	12 ,,				

GROUP III (15 cases).

146	210/150	0.35	5 days	42	190/120	1.2	8 mths.
51	195/105	0.35	5 mths.	134	190/120	1.2	15 ,,
17	—	0.9	1 week	43	—	1.3	1 week
33	200/120	0.9	1 mth.	135	180/110	1.4	1 mth.
39	150/110	0.9	11 mths.	111	210/130	1.5	12 mths.
22	180/95	0.95	21 ,,	7	180/105	1.6	4 days
55	160/115	1.0	1 mth.	65	190/120	1.6	2 mths.
90	210/110	1.0	12 mths.				

An analysis of the cases which died within two years (Table II) shows that in Group II the length of time lived increases more or less uniformly with the rise in the figures of the urea concentration test, except for No. 142, where the duration of life was a little longer than in the others. Five of the cases in this group, with a urea maximum of under 1 per cent., had not died at the end of two years—three of the cases showing a concentration of but 0.7 per cent. or under.

Taking the deaths in Group III, an interesting contrast in the length of time lived is shown by the first pair of cases (146 and 51) in the table. Although showing a urea maximum of but 0.35 per cent. at the time of the test, yet No. 51 contrived to live five months. Similar contrasts are afforded by Cases 17 and 22, and 55 and 90. This difference is brought out more clearly still by a comparison of the four cases which died within a week of the test (Table III).

TABLE III.—*Cases which Died within a Week of the Test.*

Case.	Urea Maximum.	Time Lived.
146	0.35 per cent.	5 days
17	0.9 ,, ...	1 week
43	1.3 ,, ...	1 ,,
7	1.6 ,, ...	4 days

It is thus clear that for immediate prognosis the urea concentration test by itself is of no great help. Moreover, in Group III eleven cases showing a urea maximum of less than 1 per cent. were alive at the end of the two years.

An analysis of the death rates in Groups II and III (Table IV) shows that of the cases in Group II which had a urea maximum of less than 1 per cent., half had died within two years, while no deaths occurred in that period among the cases with a concentration higher than 1 per cent.

In Group III, where the nephritis is complicated by cardio-vascular changes, the figures are not so uniform, and of the nine deaths in the cases with a urea maximum of over 1 per cent., all with but one exception had a blood pressure of over 180 mm. Hg systolic, in three of which it was over 200 mm.

TABLE IV.—*Death Rate in Groups II and III.*

	No. of Cases.	Deaths.	Percentage of Deaths.
GROUP II.			
A. With urea concentration test 1 per cent. or below	10	5	50
B. With urea concentration test above 1 per cent.	25	0	0
GROUP III.			
A. With urea concentration test 1 per cent. or below	17	6	35
B. With urea concentration test above 1 per cent.	56	9	16

The test is thus of no great value for immediate prognosis; but, always granted certain reservations, it is a very definite help in forming a general prognostic judgement upon a nephritic case.

One of the unfortunate features of the application of biological, and especially biochemical, experiment to clinical work is that the results are often expressed in numbers; and the human mind seems to have a curious eagerness to endow such figures with absolute truth, and subconsciously to make mathematical expressions take the place of a wider and more surely founded judgement.

It is obvious that in investigating a complicated "system" like the condition produced by nephritis in the human body such a test as the urea concentration test is a physiological experiment in which many factors must necessarily be uncontrolled, and one, moreover, which, strictly speaking, tells us the response of the body only at the time of the test. The condition of the kidney which we then deduce may be, of course, permanent; on the other hand, an acute exacerbation may develop upon a chronic nephritis, or a marked improvement of a subacute nephritis may occur, and therefore a single urea concentration test may be very misleading if it is regarded in any absolute way. This is but to say that clinico-pathological knowledge and judgement are not displaced by tests whose results are expressed in definite figures of so much per cent. Nevertheless, in the experience of many observers, as in our own, so comparatively crude a physiological experiment as the urea concentration test has received the pragmatic sanction of being found to work.

We would therefore conclude by summarizing our experience and opinion of the test, not merely in this admittedly restricted series of cases, but also in a large number of others in which blood analysis was available.

First, we would make it clear that we lay much more stress upon blood examination than upon any test involving urinary analysis.

The urea concentration test is quite as satisfactory as any of the urinary tests, and is, moreover, one which can easily be made in general practice. It must be interpreted only as an addition to the other physiological and pathological facts in the case.

Seeing that it is a somewhat crude physiological experiment, we shall probably be safe in taking into account only broad differences. In other words, a urea maximum of 2 per cent. or over indicates a kidney which at the time of experiment can concentrate urea satisfactorily. A urea maximum of under 1 per cent. shows a kidney which cannot. Between 1 and 2 per cent. the issue is not quite so clear, but we imagine that we shall be safe in putting it in these terms: below 1.5 per cent., strong presumption of kidney deficiency; between 1.5 and 2 per cent., possibility of renal deficiency.

Finally, in actual practice we would always have a blood analysis; but if this is not available, useful facts for prognostic judgement in a case of nephritis are afforded by the following routine:

(*a*) An analysis of the urea content of a series of specimens of ordinary urine. If these show an adequate urea percentage, then obviously a urea concentration test is not necessary.

(*b*) If the test is necessary, then the practitioner can make it himself, and form a judgement by adding the result to his other clinical facts. It is obvious that this judgement will be revised or confirmed by the further watching of the patient, the frequent observation of the urine and its urea content upon a known diet, and occasional repetition, when necessary, of the urea maximum concentration test.

THE RECORDING OF PERIMETRIC TRACINGS.

BY
FREELAND FERGUS, M.D., LL.D.,
HONORARY SURGEON, EYE INFIRMARY, GLASGOW.

UNTIL comparatively recently, perimetric tracings have usually been taken with a circular arc of 180 or even more degrees, the eye of the patient being adjusted so as to occupy as nearly as possible the centre of curvature of the arc. In my early studies I happened to be with a teacher who often used a plane surface—in his case a large blackboard—for the purposes of perimetry. When he did so he was, of course, using a tangent perimeter. This tangent method seems to have gone almost entirely out of use till it was revived some years ago by Bjerrum in his screen. More recently attention has been called to the advantages of tangent perimeters by several other authors, and notably by Drs. Sinclair and Traquair of Edinburgh.

The chief disadvantage of the tangent perimeter is that in the extreme periphery the tangent increases very rapidly, for the limiting value of the tangent of 90° is infinity, while that for 45° is unity. In the circular perimeter this difficulty is avoided, the graph being one in polar co-ordinates.

One of the advantages of the screen perimeter lies in the fact that as the eye which is being examined is not placed at the centre of a curve but at any point the examiner chooses to select, by increasing the distance between the screen and the eye the field corresponding to the retinal image may be conveniently magnified. This magnification tends to much greater accuracy of work, and tangent

perimeters seem to be admirably adapted for the delimitation of scotomata.

Many years ago (1888) Dr. George Mackay, also of Edinburgh, exhibited at the Glasgow meeting of the British Medical Association a large circular perimeter, which perhaps fulfilled to some extent the purposes of a large tangent screen. As has been shown, the ordinary circular perimeters often fail to reveal important defects in the field of vision, which at once become apparent when the more reliable tangent screen method is used. Those who have used screens for the investigation of the centre of the field, say from zero up to 50°, have no doubt of their superiority for that purpose.

In using tangent perimeters, for the reasons above stated, it is desirable to have the patient at a considerable distance from the centre of the screen. At the distance of only half a metre the tangent perimeter does not possess much advantage over a circular perimeter with a radius of curvature of half a metre. If the distance of the patient's eye be a metre from the fixation point on the screen, then for 45°, as the tangent of 45° is unity, the screen must in all directions extend to one metre from the central fixation point. For a distance of two metres a screen would require to measure, for an angular opening of 45° in all directions, at least 200 cm. from the fixation point. That, of course, at once shows the limited use which can be made of tangent screens, because, even with a spacious room, it is impossible to get 70 inches between the fixation point and the floor; moreover, the patient's eye should be as nearly as possible on a level with the fixation spot. For the thorough examination of the centre of the field of vision the tangent perimeter will be found to be most serviceable. In the usual forms supplied for recording perimetric examinations there is the same distance between zero and the circle representing 45° as there is between the circle representing 45° and that representing 90°, also the same distance between zero and 30° as there is between 30° and 60° and as there is between 60° and 90°. So long as the examiner recognizes the fact that he is dealing with polar co-ordinates and can translate their meaning then no great harm will accrue. But one advantage of tangent perimeters, where applicable, is that they give the field of vision without any need of interpretation.

Dr. Sinclair of Edinburgh, and probably other workers, have availed themselves of tangent scales. A tangent scale can be easily prepared for any radius, such as that of a metre or of two metres, or any other measurement that may be required; but I think that nothing more is necessary than to take a note of the field given by a tangent perimeter in ordinary rectangular co-ordinates. The screen perimeter I use is black, and on it are traced in black tape the ordinary x and y co-ordinates. There is nothing to prevent the whole screen being divided up by such pieces of tape into little squares, the length of the side of each little square being two inches or even less, according to the breadth of the tape.

In the first quadrant both the abscissa and the ordinate are positive; in the second the abscissa is negative and the ordinate is positive; in the third quadrant both the abscissa and the ordinate are negative, and in the fourth the abscissa is positive and the ordinate is negative. Now with such a perimeter all that has to be done is to note accurately the values for x and y of every point taken in the boundary of a scotoma. There is no need whatever to transfer it to polar co-ordinates. Of course, should any such need arise, the calculation is of the most simple kind provided the distance at which the patient was placed from the fixation point has been accurately noted.

This simple method seems to avoid a considerable amount of trouble, and has the advantage that no special diagram requires to be made for the recording of the results; ordinary ruled paper, such as is commonly used for graphs, is all that is necessary.

ICTERUS WITHOUT HAEMOGLOBINURIA AFTER QUININE TREATMENT.

BY

G. R. ROSS, M.B., CH.B., PH.D.,

RHODESIAN RESEARCH FELLOW, LONDON SCHOOL OF HYGIENE AND TROPICAL MEDICINE;

AND

G. H. PEALL, M.B., B.S.LOND., F.R.C.S.ED.

(From Salisbury Hospital, Salisbury, Southern Rhodesia.)

THE part played by quinine in the genesis of haemoglobinuria has received the attention of many investigators, and the opinion has been expressed that in certain cases it can act as the precipitating agent of the attack. Castellani and Chalmers, indeed, in their textbook, consider the relationship so intimate as to warrant quinine haemoglobinuria being defined as a clinical entity apart from true haemoglobinuric fever. There seems, however, no justification for this from the clinical point of view, since the symptoms and course of the disease are essentially the same in both.

Stephens and Stott (1915) have collected a record of 103 cases in which the intimate relationship between the administration of quinine and haemoglobinuria could not be ignored; while Thomson (1924) has more recently published records of two cases in which the correlation was most striking. The consensus of opinion would seem to be that while quinine in many cases does not play a leading part in the genesis of haemoglobinuria, cases do occur in which it seems to act definitely as the immediate cause.

How quinine may bring about haemoglobinuria will not be discussed further than to say that it is generally accepted that the haemoglobinuria is secondary to a haemoglobinaemia brought about by the lysis of erythrocytes in the blood stream. Plehn (1920), mainly on histological grounds, has disputed this theory of intravascular haemolysis in haemoglobinuria, and considers that the haemolysis takes place in the renal tubules. Salvioli (1922) and Ziemann (1926), however, working on the same lines as Plehn, were unable to confirm his findings.

Barratt and Yorke (1909), on the other hand, have brought forward evidence pointing to the blood stream as the site of lysis. In a series of observations on blackwater cases they found that in certain cases the percentage of haemoglobin free in the plasma was considerably higher than in normal controls. In others, however, the figure approximated to that found in health, but they consider that this does not necessarily refute their assumption of intravascular haemolysis, since, owing to the relatively long intervals at which patients may pass urine, it may quite well be that, although the urine does contain haemoglobin, active excretion of it may have ceased. Arkwright and Lepper (1918) and Dudgeon (1920) have reported similar findings.

While direct proof of haemoglobinaemia may be lacking, it is possible to obtain information indirectly that supports this hypothesis. Thus an increased content of substances in the blood stream which are known to be derivatives of haemoglobin would point to an intravascular haemolysis.

It is now generally accepted that haemoglobin is broken down in the cells of the reticulo-endothelial system, particularly, if not wholly, by the Kupffer cells which are found in the liver sinuses, and is converted into bilirubin and haemosiderin. Thus, in conditions in which haemolysis exists, an increased output of bilirubin can be anticipated. That this is the case in malaria, in which blood destruction in excess of normal exists, has been shown by van den Bergh (1924), Hughes (1924), and Kingsbury (1926). Van den Bergh's test is now so widely employed that it requires no description, but it may be emphasized that not only does it afford a measurement of the amount of bilirubin present but it also distinguishes between what might be termed mature and immature bilirubin in the serum. Mature bilirubin is that which has passed through the polygonal cells of the liver and has then been absorbed into the blood stream, and is present in cases of obstructive jaundice. This variety gives the direct reaction. If, however, owing to rapid blood destruction, bilirubin is

produced at so rapid a rate that the polygonal cells are unable to deal with it *in toto*, the excess is absorbed directly into the blood stream from the Kupffer cells, and forms the immature bilirubin which gives the indirect reaction. An indirect reaction should, then, be obtained in those cases where the pathological factor is increased blood destruction, and it is this variety which occurs in pernicious anaemia and malaria. Such a reaction can be accepted as evidence of intravascular haemolysis.

In haemoglobinuric fever, in the initial stages of the disease, the indirect reaction is strongly positive and the number of units of bilirubin present shows a huge increase on the normal amount of 0.2 to 0.5 unit found in normal controls (unpublished results of one of us, G. R. R.). We have thus indirect evidence that haemoglobinuria in haemoglobinuric fever is accompanied by haemoglobinaemia. There can be no doubt that the haemoglobinaemia must precede the haemoglobinuria. Assuming, then, that haemoglobinaemia exists, it can be postulated that two mechanisms at least come into play in the endeavour to rid the body of the haemoglobin dissolved in the plasma. At first there is an increase in the activity of the reticulo-endothelial system, so that as much as possible of the haemoglobin may be disposed of by the normal methods of converting it into bilirubin. This we know does happen. If, however, the amount of haemoglobin is in excess of the maximum with which the reticulo-endothelial system can deal, then excretion by the kidneys occurs, with consequent haemoglobinuria. We can thus assume that there exists a threshold value for haemoglobin; whether that is constant or whether it varies from individual to individual is not as yet clear. It cannot be assumed at present that the reticulo-endothelial system, on the activity of which the threshold value must in part depend, functions equally in every individual. It is, however, known that if the haemolysis be slow and gradual, as in pernicious anaemia, or even sudden but relatively slight, as in malaria, haemoglobin does not appear in the urine.

Turning now to the question of quinine haemolysis *in vivo*, it is conceivable that if quinine can produce haemolysis sufficient to cause the appearance of haemoglobin in the urine, cases might occur in which the degree of haemolysis is so slight that the free haemoglobin can be disposed of entirely by the reticulo-endothelial system without the appearance of haemoglobinuria. References to this possibility are relatively few. Koch (1898) stated that after the administration of quinine an attack of icterus may occur. Blacklock (1923) believes that haemolysis with slight jaundice can occur without haemoglobinuria and that this condition is frequently due to the same cause as blackwater fever.

The following case is reported as an example of haemolytic jaundice after quinine treatment without the development of haemoglobinuria.

A male European, aged 11, was admitted to Salisbury Hospital under the care of one of us (G. H. P.) as a "pre-blackwater case" on March 4th, 1926. A history was obtained of repeated attacks of malaria throughout the previous six months. The patient was pale, sallow, and thin. He exhibited characteristic malarial cachexia with lemon-yellow conjunctivae. There was, however, no clinical jaundice in the true sense of the term. A blood examination on the day of admission gave the following result: Red blood corpuscles 1,300,000 per c.mm., white blood corpuscles 5,700 per c.mm., haemoglobin 39 per cent. The red cells did not exhibit any abnormality except occasional polychromasia. A differential count showed: Polymorphonuclears 56 per cent., lymphocytes 21 per cent., mononuclears 20 per cent., eosinophils 2 per cent., transitionals 1 per cent. No malarial parasites were seen.

Examination for parasites was also negative on March 6th, 7th, and 9th. The spleen was enlarged to two fingerbreadths below the costal margin. The treatment adopted was on general lines, including the exhibition of liquor arsenicalis and sodium bicarbonate with ample quantities of fluid fluids. On March 9th, acting on the assumption that antimalarial treatment was indicated, quinine therapy was instituted, starting with extremely small doses in view of the possible onset of haemoglobinuria.

Thus on March 9th 1/32 grain of quinine bihydrochloride was given; on March 12th the dose was increased to 1/32 grain thrice daily, on March 14th to 1/16 grain thrice daily, on March 15th to 1/8 grain thrice daily, on March 18th to 1/4 grain thrice daily, on March 19th to 1/2 grain thrice daily.

On March 20th the patient complained of severe headache, nausea, and splenic pain. The spleen was now four fingerbreadths below the costal margin. There was slight vomiting, and the temperature, which had been rather febrile for about a week, rose to 100.2°, and on the two succeeding days reached maxima of 100.8° and 100.6°. On the morning of March 21st the patient was obviously jaundiced, and in the course of a few hours became intensely so. Blood counts done on this day gave the following results: Red blood cells 1,250,000 per c.mm., white blood cells 6,000, haemoglobin 35 per cent. Fouchet's test for bile pigment in the serum was positive. The van den Bergh test gave a positive indirect reaction, and the number of units of bilirubin present, as estimated by the Tannhäuser and Andersen technique, was 2.5. Blood smears were examined on March 21st, 22nd, 23rd, and 24th, but the red cells showed no abnormality and malarial parasites were absent.

Quinine was immediately stopped and the icterus completely disappeared in the course of two days. The temperature came down to normal, and the pulse, which in the pre-icteric period had varied between 80 and 90, and which during the icterus varied between 120 and 140, returned to its former level. The stools were normally coloured throughout the icterus. An estimation of bilirubin made on March 24th showed 0.75 unit to be present in the serum, which is slightly in excess of normal.

The patient was given injections of sodium methylarsenate and was kept under observation for a period of fourteen days, during which no untoward symptoms developed. The urine was examined daily, in twenty-four hour specimens, for blood pigment, during the icteric period, by the benzidine test and spectroscopically; the results were invariably negative. Urobilin was never present in a greater dilution than 1 in 10 (Marcussen and Hansen technique).

This case, in our opinion, is an example of an intravascular haemolysis, evidenced by jaundice, but with no accompanying haemoglobinuria. There can be no doubt that the jaundice was haemolytic in type. As regards the relationship of quinine to the intravascular haemolysis, it is true that the icterus did not make its appearance clinically until the twelfth day after the institution of quinine treatment, but it must be remembered that the sallowness of the patient and the lemon-yellow conjunctivae, so characteristic of chronic malaria, prevented the appreciation of slight additional degrees of icterus.

Again, the dosage of quinine was exceedingly small; only 1½ grains were being given daily, and only 5½ grains had been administered altogether when the jaundice became clinically apparent.

The disappearance of the icterus on the stoppage of quinine treatment affords additional support to our belief that the quinine acted as a haemolytic agent.

The interest of the case, however, lies mainly in the fact that, while intravascular haemolysis sufficient to produce marked clinical jaundice had taken place, haemoglobinuria did not develop.

DETOXICATION IN THE TREATMENT OF BURNS.

BY

W. R. WILSON, M.B., B.CH.CANTAB.,

LATE SENIOR HONORARY SURGEON TO DONCASTER ROYAL INFIRMARY.

DETOXICATION, as part of the treatment of burns and scalds, has not received the attention it deserves, though burns owe most of their deadliness to toxaemia. In the course of prolonged inquiries in many directions I have come across only one man who had used a dressing with detoxicating properties; this was an application of ichthyol and glycerin, covered over with boric fomentations. None of the younger men had heard of such treatment, which is the more remarkable in view of the great advances made in the treatment of infected wounds during the latter part of the war.

In most hospitals burns are treated in the surgical wards, but since there appears to be nothing to do after treating the initial shock and ordering an admittedly unsatisfactory dressing, a "burn" becomes a purely medical case. The patient has a grave systemic disturbance which is not to be benefited by any surgical measures, unless possibly blood transfusion. There is, however, a method of local treatment lying ready to our hands, and only waiting to be applied. It is a great deal easier to prevent poisons from entering the system than it is to get them out before they can do harm, and it is more rational.

Toxaemia, it should be realized, comes on very quickly —long before septic processes have had time to become established. It is caused solely at first by the products of decomposition of the proteins of the tissues which the heat or chemical has killed. According to Dale, in a recently published lecture on the function of the capillaries in the control of the circulation (*University of London Press*, p. 18), "a simple extract, made by boiling the fresh tissue of almost any organ of the body, will be found to contain some substance or substances having this histamine-like action"—histamine being one of the definitely identified and intensely poisonous substances that are formed in protein decomposition. These substances cause relaxation of capillary tonus and general collapse of the patient. Further proof, if it were needed, that local exudations do find their way quickly into the general circulation is afforded by observations on patients who happen to be anaphylactic to such substances. In them the characteristic phenomena will appear within an hour or two, to be relieved again as quickly by applying the treatment to be described.

The first indication, then, is to induce abundant serous exudation, and the second is to get it away from the damaged surface. Wax (containing antiseptics) no doubt forms a valuable first-aid covering, but a patient upon whom I tried a prolonged course of this dressing developed tetanus and died. Such an application is obviously useless as a detoxicating agent. As for oil, how can a dressing impregnated with it, or any greasy ointment, soak up poisonous exudate, even if it be on the surface and awaiting removal? Baths have been advocated, but I have heard of none other than of plain water or normal saline. Picric acid has antiseptic properties, but how can it fulfil the above two indications? It is applied in hypotonic watery solution, or even with the addition of something more hypotonic still—namely, alcohol. Its advocates say: "Keep the skin dry and change the dressings as infrequently as possible." How is that to prevent the absorption of the poisons from the layers that are just too deep to be affected by the drying process? Decomposition progresses there unhindered, and there is nothing to divert the foul products from travelling inwards. Such desiccation can at best be only superficial. Another aqueous dressing that is used is solution of aluminium acetate (1 per cent.), but it is found to be of little value in limiting sepsis, and obviously it will fail in the osmosis test.

The only substances I have used to provoke osmosis towards the surface are sodium chloride and glycerin. Professor McLeod of Leeds has tested them for me in various concentrations against fresh red cells. He found that with sodium chloride it was possible to go up to 4 or 5 per cent. without readily haemolysing, but he found glycerin haemolytic in all strengths from 2 per cent. upwards. Nevertheless, the presence of sodium chloride of 3 to 5 per cent. along with it afforded appreciable protection to the cells. Other substances more suitable may be found, but there is no gainsaying the physical effectiveness of the two mentioned. Professor McLeod tried magnesium sulphate and sodium sulphate also, but found the results variable, owing to difference in composition. Both salts are capable of holding two different quantities of water of crystallization.

I have used this method in four or five bad cases.

CASE I.

A girl, aged 18, received burns over about two-thirds of the surface of both legs and thighs and her buttocks. Within a few hours she began to vomit—the next grave symptom after the initial shock. The special dressing was applied and the vomiting ceased within three or four hours, and she was able to take plenty of food. She improved steadily week by week till some six or eight weeks later, when I consented to a less troublesome form of dressing being tried—namely, boric fomentations. Care was to be taken to keep them hypertonic, by adding no more water to the lint than was needed to wet it. (A semi-saturated solution of boric acid is, I believe, isotonic.) The result was tragic. Vomiting began again within a few hours, and the patient died the next day.

CASE II.

This patient was a child, who was burnt about the chest, shoulders, and neck. He was in hospital three months or more, and several times the lines originally laid down for treatment were departed from. Ointment, though less painful in use, was always accompanied by a change for the worse in the general condition, and much the same happened with boric fomentations.

CASE III.

This patient was a healthy young farmer who weighed 19 st. His injuries were caused by the accidental ignition of petrol, and, as in the first case, they affected chiefly the backs of his legs, thighs, and buttocks, though his face and hands were touched also. I saw him about an hour and a half after the accident. There was then little evidence of shock, though he was in a good deal of pain. I gave him 1/4 grain of morphine hypodermically and wrapped him up in blankets over what clothes he still had on—his legs were burnt quite bare—and sent him to a nursing home. The remaining portions of his clothing were removed without an anaesthetic, and the special dressings applied to all burnt parts. He vomited four times during the first night, and twice more in the next twenty-four hours, and that was all. The skin sloughed over larger areas for its whole thickness, and behind the knees and on the left calf the burns were deeper still, one tendon being exposed. Although his evening temperature was about 100° F. for the first fortnight or so, his appetite was good throughout. He ate well of fish and such-like light diet, and drank large quantities, for he was often genuinely thirsty. Towards the end of his seventeen weeks in the home he was touched up in a few places with blue-stone and had a few applications of direct sunlight. Apart from these he had no treatment other than hypertonic saline containing also eusol and glycerin. He made a perfect recovery, without undue scarring.

CASE IV.

A child, aged about 12, was scalded over the lower abdomen and thighs through the tearing of a rubber hot-water bottle. She did not do well, dying at the end of three weeks with bronchopneumonia and a scarlatiniform rash. The solution used for the dressings was eusol of one-quarter of standard strength, containing also glycerin to the amount of 11 per cent. by volume and sodium chloride 2½ per cent. The burnt surfaces never looked healthy. I think now that she had a great deal too much glycerin and too little sodium chloride.

CASE V.

The only other case extensive enough to record was that of a girl, aged 22, who spilt boiling water down the side of her leg. I could not observe her progress closely, but she had neither glycerin nor eusol, but boric lint moistened with salt solution of about 4 per cent. She made good and rapid progress all the time.

I prefer eusol as a germicide for two reasons. The first is the obvious one that it really is germicidal, provided only that it is not destroyed by overheating—even by pouring hot water into it. The second is that any harmful effect it has on the tissues is only intermittent in character, owing to its instability. Its characteristic odour is gone in two hours or less in spite of a covering of jaconet, after which the dressing remains as an aseptic one only. I think it ought to be used for the first few days in every case, though the experience of my last case seems to suggest that an antiseptic stronger than boric acid is possibly not needed at all with this method.

Hypertonic dressings need to be changed frequently, for in remaining they rapidly lose this special property, besides endangering the cleanness of the bed. A macintosh is essential. The dressings should be thoroughly wet when applied, and may be expected to be absolutely dripping when taken off, besides leaving pools on the macintosh sheet. My third patient used to complain pretty regularly of increasing discomfort whenever a dressing had remained on three hours. He would ask to be re-dressed, in spite of the pain attached to the process.

Convenient solutions can be prepared thus:

	I.	
Standard eusol solution	...	1 part (20%)
10 per cent. saline solution	...	2 parts (NaCl 4%)
Water	...	2 parts
	II.	
Standard eusol solution	...	1 part (25%)
10 per cent. saline solution	...	1½ parts (NaCl 3.75%)
Water	...	to 4 parts

Memoranda:

MEDICAL, SURGICAL, OBSTETRICAL.

THE OPERATION OF TONSILLECTOMY.

A DESCRIPTION of the ambidextrous method of tonsillectomy may interest those unfamiliar with it.

Doyén's gag is introduced from the right side and ethyl chloride is administered. The surgeon stands behind the patient's head, which is drawn over the end of the table. A blunt guillotine (McKenzie's or Heath's) of suitable size is selected, and a La Force adenotome is laid ready to hand. In "slow motion" the subsequent steps are as follows.

If the right tonsil is to be removed first, the guillotine is held in the left hand. With elbow raised and wrist pronated it is passed, handle upwards, into the pharynx, elevating the tongue. A momentary inspection of the fauces is made.

The second combined movement in three planes resembles a parry in fencing: supination of the forearm rotates the instrument through a right angle, abduction of the hand carries it obliquely across the patient's mouth, and flexion of the elbow dislocates the tonsil forwards for about an inch.

The third stage is commenced by levering the anterior pillar of the fauces inwards with the palmar aspect of the right forefinger until the sulcus around the tonsil can be engaged by the cutting edge. As the left thumb presses the blade home the right forefinger is swept firmly upwards towards the root of the tongue, pressing the whole tonsil through the ring.

A final circling movement, which brings the guillotine back to its original position, handle upwards, is continued by steadying the instrument with the right hand, thrusting it a short way down the throat, and withdrawing it, together with the enucleated tonsil.

The guillotine is transferred to the right hand and manipulated in a corresponding manner for the removal of the left tonsil.

The adenotome is passed into the pharynx with the right hand. Retracting the soft palate with the left forefinger, the handle of the instrument is carried towards the patient's chest, so that the other end glides upwards. Pressing firmly on the posterior nasopharyngeal wall, the blade is thrust home, removing intact the adenoid mass, in which deep vertical clefts are apparent.

The patient is turned over on the right side and cold compresses are applied to the face.

W. O. LODGE, M.D., F.R.C.S.Edin.,
Ophthalmic and Aural Surgeon, Royal Halifax Infirmary.

INTESTINAL OBSTRUCTION FROM UNDIGESTED POTATO.

ILEUS in association with foreign bodies in the intestine is familiar, the commonest foreign body being, of course, a gall stone. It is rare, however, for foodstuffs to survive the softening influence of gastric digestion, to pass the pyloric sphincter, and to escape into the intestine in sufficient bulk to produce an actual obstruction. The case here reported will serve to illustrate that acute obstruction may result from this cause.

A hawker, aged 66, had a meal in a common lodging-house at 10 o'clock one Sunday night. He ate heartily of a dish consisting of meat, potatoes, and suet, and recollected gulping chunks of food, the cooking of which was not above suspicion. About 1 o'clock the following morning—that is, three hours after his meal—he was wakened by severe pain, and about an hour later he vomited. Occasional vomiting and colicky pains continued until his admission to hospital, about eighteen hours after the commencement of the illness.

He was a spare, but tough, man. The pulse was 72 and the temperature 99° F. His teeth were in a deplorable state, and he was not possessed of any adequate chewing mechanism. When first seen he had little pain. The abdomen was not distended, nor was there visible peristalsis. Abdominal palpation afforded no clue. Rectal examination was negative, and examination of the hernial sites disclosed no abnormality. Repeated enemas emptied the lower bowel, but, thereafter, neither faeces nor flatus were passed. In view of the history, and of the fact that the pulse was not rising, it was resolved to wait. In the early hours of Tuesday morning the vomiting became frequent, copious, and definitely faecal in character. The abdomen remained flaccid. A diagnosis of intestinal obstruction was made, and at 10.30 a.m. the abdomen was opened. On passing the hand into the pelvis a rounded hard mass, at first thought to be a gall stone, was felt in the lower ileum. The intestine, which was healthy and of about normal calibre, was delivered through the wound, incised, and the foreign body removed. Examination proved it to be a hard, partly cooked, wart-like mass of potato weighing 14 grams. Its size was, in itself, insufficient to produce obstruction, and there is no doubt that it would have easily passed along had the intestine been at all dilated. Local spasm of the gut was the deciding factor in the production of the blockage. After suturing the intestine the abdomen was closed. Recovery was uneventful, and the patient left hospital for a convalescent home on the fourteenth day.

A possible sequence of events can be made out in this case. Severe pain commenced three hours after the meal; and was probably associated with the passage of the potato through the pylorus. Once in the small bowel peristalsis was able to move the foreign body as far as the lower ileum, until, progress retarded, a second obstructive attack, accompanied by faecal vomiting, occurred.

W. E. M. WARDILL, M.B., B.S., F.R.C.S.,
Surgical Registrar, Royal Victoria Infirmary, Newcastle-on-Tyne.

OSTEOMYELITIS OF RIB.

CASES of acute osteomyelitis of ribs are so uncommon that an account of the following may be of interest.

A boy, aged 16, was admitted to the Eccles and Patricroft Hospital, Manchester, on July 23rd, 1926, complaining of pain in the left side of the chest. This had come on ten days previously. There was no history of injury. The pain was most acute on the left side towards a point in the anterior axillary line over the fifth rib. The boy was acutely ill, with a temperature of 103°, pulse 108, and respirations 28. He was sweating profusely and there was a strong sourish smell that was not unsuggestive of rheumatic fever. There was a swelling over the fifth rib extending from axilla to sternum; it was exquisitely tender to touch and was pulsating, owing to transmitted impulse from the heart. The whole of the chest in the region of the swelling was dull to percussion, and it was impossible to define the area of cardiac dullness. The swelling was explored with a needle and free pus withdrawn.

Operation by Mr. Jefferson.

Anaesthesia was produced by open ether, and an incision four inches long was made over the swelling and deepened until pus was found; some 8 to 10 ounces escaped. Pus was seen to be welling up through an opening in the intercostal muscle, and the upper part of the fifth rib in the neighbourhood of the aperture was bare of periosteum. Three inches of the rib were removed. Pus was seen to ooze out of the rib medulla as the bone was cut through. The inner layer of periosteum was found to be largely destroyed. The deeper wall of the cavity appeared to be composed of fine vascular adhesions over the pleura. These were not disturbed for fear of pleural infection. The inner abscess wall pulsated freely with the heart beat.

The pathologist reported infection by *Staphylococcus aureus*. The infection did not spread to the pleura, and uninterrupted recovery followed.

One point of interest was that the infection appeared to have begun in the rib near to its union with the costal cartilage, and in this matter conforms with the rule observed in osteomyelitis of the long bones. The disease begins on the metaphyseal side of the epiphyseal line.

An account of acute osteomyelitis of ribs was published by Parcelier and Chauvenent of Bordeaux.[1] They gave an account of six cases and showed a table of 83 recorded cases; a pathological report was available in only 32. The pathology of this condition does not differ from osteomyelitis of the long bones. The typhoid bacillus was found once, and the pneumococcus twice.

The first case of primary osteomyelitis of ribs was recorded by Jaboulay in 1885. Michelson[2] quotes 16 personal cases. Fantozzi could find but one case over a period of twenty-five years.

It seems that the condition is seen more often between the ages of 10 and 16, and in boys rather than girls. The left side is more often affected. The seventh rib is the commonest site, then come the fifth and ninth respectively.

I am indebted to Mr. Jefferson, consultant surgeon at Eccles and Patricroft Hospital, for permission to publish this case.

Reports of Societies.

POLYCYTHAEMIA VERA.

A CLINICAL meeting of the Devon and Exeter Medico-Chirurgical Society was held on December 10th, 1926, when the President, Mr. R. WORTHINGTON, was in the chair, and Dr. F. A. ROPER showed a case of polycythaemia vera —Vaquez's disease.

Dr. Roper said that the patient, a man aged 59, had given a history of shortness of breath with fainting attacks over a period of three and a half years; he had the typical cyanotic complexion, and there was a considerably enlarged spleen. The red cells numbered 12,840,000 per c.mm., and the leucocytes 11,900, the haemoglobin being 110 per cent. Dr. Roper explained that the infection consisted of a hyperplasia of unknown origin of the erythroblastic tissues. The same blood picture occurred to a partial extent in emphysema, congenital heart disease, and among those sojourning in high altitudes. Fainting attacks and shortness of breath, as in this case, were the earlier symptoms, and should be attributed to the increased viscosity of the blood. Nephritis, oedema of the extremities, and ascites might be expected in the later stages.

Dr. W. GORDON alluded to a case he had seen in Vienna, where a similar condition of the blood was produced by syphilitic disease of the pulmonary vessels. This particular affection was sometimes known as Ayerza's disease, whereas it should be generally accredited (instead of alternatively as now obtained) to Osler, who originally described it. Dr. Gordon mentioned the value of benzol in the treatment, and congratulated Dr. Roper on having brought to the notice of the meeting a typical instance of a most interesting and most uncommon condition.

Dr. D. MILLER MUIR said he would like to see the effect of x rays on this case. In a similar one the treatment was not completed, and he was not able to form an opinion as to its value.

Dr. ROPER, in replying, agreed to the value of the benzol group, and in reply to Dr. Miller Muir said that x rays in association with benzol might be given a trial. With this combination he had seen a considerable reduction of leucocytes in a case of splenomedullary leukaemia.

Clinical Cases.

Dr. ROPER showed also a case of hyperthyroidism with glycosuria in which considerable progress had been made with insulin treatment. The patient, a man aged 26, was admitted to hospital with pronounced muscular weakness, wasting, and diffuse thyroid enlargement. Glycosuria appeared some four weeks after admission, during which period he had continued to waste. Under treatment with insulin he gained 2 st. in weight *in three months*. The blood sugar curve after a glucose test meal was atypical and acidosis was absent. Insulin was commenced with 10 units and increased to 34. The *man was not placed on a special* diet. There was still a trace of glucose in the urine. Dr. Roper explained that experiments on animals had proved that insulin definitely lowered the *metabolic* rate by virtue of the resulting hypoglycaemia, whereas the metabolic rate was increased in *hyperthyroidism*.

The PRESIDENT showed, *in conjunction with* Mr. A. L. CANDLER, a case of mastoid abscess with sinus thrombosis and secondary pyaemic arthritis of the knee-joint in a girl aged 14. Operation revealed considerable suppuration, with invasion of the lateral sinus, the latter being packed; two days later the symptoms had necessitated ligature of the internal jugular and a wide opening of the lateral sinus. In spite of this a rigor occurred in twenty-four hours from the operation, and six days later was followed by pain and swelling in the right knee-joint, which was aspirated, staphylococci being found. Ether was injected into the joint and collosol iodine given intravenously. The patient was now convalescent, and the wounds had almost healed; the knee-joint, although still a trifle enlarged, was perfect as regards movements. An additional point of interest was the occasioning of the secondary joint infection without definite evidence of an immediate pulmonary lesion.

Dr. R. EAGER showed a girl, aged 19, with Parkinsonian symptoms; the case was typical of the post-encephalitic group, *although the history of the acute illness was not* clearly established. The earliest manifestations had followed an attack resembling influenza some three years previously; the patient became unemployable, drifted into a Poor Law infirmary, and from thence was transferred to the Devon County Mental Hospital. On admission she was depressed, unable to sit up, and took no interest in her surroundings. There was rigidity of muscle, double ptosis, mask-like symptoms, and excessive salivation. Under hyoscine there had been a distinct improvement as regards the lethargic condition, and the salivation had been held in check by belladonna. Dr. Eager remarked that the chronic lethargic stage which followed the acute delirious stage of encephalitis was not infrequently mistaken for hysteria; there were periods of unusual activity, and then relapse once again into the lethargic stage. This girl was an example of the alternating type, and had surprised those in charge of her by winning a race last summer. Dr. Eager also drew attention to the alteration in temper in these cases, and to the tendency to become impulsive; it was thus sometimes necessary to distinguish between post-encephalitic symptoms and dementia praecox.

Dr. A. L. CROCKFORD showed an infant, aged 5 months, with multiple meningocele in the occipital region. The protrusions were about the size of a large cherry, and in all other respects the infant was normal and in good health. During a two months' observation no fits or other symptoms had occurred to suggest cerebral irritation. Dr. Crockford had felt uneasy about the central tumour. Mr. DYBALL *considered that multiple meningoceles were rare*, and especially so in the occipital region. He counselled an expectant line of treatment for the present, with the hope that Nature would close the cleft.

Mr. B. DYBALL showed a young man who had had a swelling in the right iliac fossa. Originally the radiogram showed an obstruction apparently in the proximal part of the transverse colon, and an operation had brought to light a primary growth at the ileo-caecal valve. The diseased caecum had become attached to a freely movable transverse colon. A secondary growth was also noted on the colon, some two inches of normal intestine intervening between this nodule and the point of adhesion to the caecum. The caecum and diseased gut were freely resected and ileo-colostomy performed. The man had made an excellent recovery, and Mr. Dyball considered that the prognosis was very hopeful. Dr. JACKSON mentioned two cases admitted to hospital with similar symptoms, and where a diagnosis of caecal growth had been made; in one the diagnosis had proved correct at the operation, but in the other the mass had been found to be a displaced kidney.

Mr. DYBALL also showed a man, aged 29, who, *in falling* 20 ft., injured the right leg, and was admitted to hospital with pain in the right hip, crepitus over the great trochanter, half an inch shortening, and outward rotation. *The radiogram* showed a trochanteric fracture, and in view of the uncontrolled eversion and rotation operation was performed and the fragments screwed together. Mr. Dyball said that these fractures were very rare, and that in addition to the uncontrolled movements there was considerable blood clot in the joint, which in itself often proved a barrier to reduction.

Mr. DYBALL further showed a man (middle aged) *with* multiple papillomata of the bladder; the first operation for this had been performed in 1920 by the suprapubic route. Haematuria had occurred in November, 1926, and on admission to hospital cystoscopy had shown several growths. Suprapubic cystotomy was performed, and one large papilloma and four or five smaller had been excised; their bases were treated by diathermy. The bladder wall was closed and the bladder drained by indwelling catheter. Mr. Dyball, in replying to questions, said that the size and pedicle of the tumour revealed by cystoscopy determined him in choosing the *suprapubic route*, and in any case the scattered growths would have taken many long sittings to eradicate thoroughly per urethram. He appreciated the disadvantage of the suprapubic method in that the bladder was less easily maintained filled with fluid, and thus arose the liability to reimplant the villi, but in this instance it had been possible to carry out the precaution efficiently.

The growths were too far apart to make resection a practical consideration.

Mr. R. WAYLAND SMITH showed a man, aged 27, with spastic paralysis of the left arm dating from birth. The hand was acutely flexed at the wrist, and was quite useless. An interesting feature in this case was the automatism in the left hand, any movement performed by the right hand being attempted simultaneously and involuntarily by the left. Mr. Wayland Smith also showed a man in whom there was complete transposition of the viscera of the chest and abdomen, the latter being further demonstrated by skiagrams taken after a bismuth meal.

AN OBSCURE UTERINE NEOPLASM.

AT a meeting of the North of England Obstetrical and Gynaecological Society in Leeds, on December 17th, 1926, the President, Mr. W. GOUGH (Leeds), delivered a valedictory address entitled "Some reflections," and Dr. D. DOUGAL (Manchester) described an unusual diffuse uterine tumour.

Dr. Dougal said he had removed the specimens exhibited from a single woman, aged 43, whose main symptom was persistent haemorrhage for about five months. Previous to this she had lost somewhat excessively at the menstrual periods for about a year. She had very little pain. A diagnosis of uterine fibroid was made, and the uterus was removed subtotally with the left appendage, the right ovary being left. The uterus was enlarged and globular, about the size of a two months' pregnancy, and very hard. An incision was made through its anterior wall during the operation, and it was found that the tumour was not encapsuled, but diffuse with polypoid extensions into the cavity. It was thought at this time that the tumour was probably an adenomyoma becoming submucous, and no malignancy was suspected. The patient made an uninterrupted recovery, and was discharged in between two and three weeks. On examining sections from the tumour it was found that the original diagnosis of adenomyoma was wrong, as there were no obvious glandular structures to be seen in any of the sections. Dr. Dougal had thought this very unusual, and could find no reference to any growth of this kind until he was informed of an article written in 1919 by Casler, describing a similar case. A drawing of the uterus made on the day of operation gave a very good idea of the naked-eye appearances. The tumour was in the fundus of the uterus, slightly on the posterior aspect. It was a diffuse growth, and consisted of fibro-muscular trabeculae, among which were scattered islands of softer tissue. These islands projected from the surface when the tumour was cut through, and gave a very peculiar appearance to it. The cut surface of the tumour had not the homogeneous cheesy appearance usually associated with sarcomata, and there was no cystic formation. The cavity of the uterus was occupied by a number of polypi, pale in colour; these, again, did not suggest sarcoma. The polypi consisted of tissue very similar to the endometrial stroma. There were many oval cells closely packed together, and at the inner part there was a good deal of blood extravasation. The polypi were covered by a single layer of columnar epithelium. *There were no glands to be seen*, and none of the cells were definitely of malignant type. Lining the unaffected parts of the endometrium there was a normal mucous membrane, but somewhat compressed, and the compression was more marked nearer the polypoid formation. Deeper in the uterine wall were islands of cellular tissue amidst the muscular bundles. Here again the cells were of the same type, and there was no necrosis to be observed. The growth seemed to have pushed in among the muscular bundles and displaced them, or, as in some parts of the section, had actually destroyed them by compression. There were areas where the stromal tissue had the appearance of travelling along veins or lymphatics, but Dr. Dougal was doubtful if this was actually the case. Nearer the serous surface some of the cellular spaces gave a somewhat different appearance. In these, in addition to the ordinary stroma cells, there were a few lines of larger cells, which appeared to be the remains of broken-down glands. The tumour was evidently either a sarcoma or a benign tumour of the endometrial stroma, which had grown first into the wall of the uterus and later towards the cavity in the form of polypi. The speaker added that the case described by Casler was of exactly similar type, and had been considered to be an endometrioma without glands.

The PRESIDENT thought that the tumour was probably an endometrioma. Professor M. H. PHILLIPS (Sheffield) had, on first examining the sections, thought it to be a sarcoma, but had changed to the view that it was an endometrioma. Mr. W. W. KING (Sheffield) said that if the endometrial stroma was invading the muscle the tumour should be described as a sarcoma.

Concealed Accidental Haemorrhage.

Mr. W. W. KING (Sheffield) described two cases of concealed accidental haemorrhage with special reference to the histological condition of the muscle. The first patient, aged 33, a multipara, eight months pregnant, had had abdominal pain and bleeding for a week; she presented the typical picture of concealed accidental haemorrhage—namely, pallor, rapid pulse, and a hard and tender uterus. There was no urine in the bladder. At the operation it was found that the uterus was plum-coloured from effused blood. There was free blood in the peritoneal cavity and large haematomata in both broad ligaments. Hysterectomy was performed, but the patient died in a few hours from shock. Mr. King's second patient was an unmarried girl, aged 22, who was not known to be pregnant until she was taken ill early one morning. She was thought to be in labour, as the cervix was dilating and there was a little haemorrhage. The uterus was noted to be hard, but not tender. The pulse was 80, but a few hours later became rapid. Jaundice was noted, and the uterus though still hard was not tender. A diagnosis of concealed accidental haemorrhage was made. The bladder was empty and no urine had been passed for twelve hours. At the operation the uterus was found to be plum-coloured and there were large haematomata in the broad ligament, but no free blood in the peritoneal cavity. Caesarean section was performed and the uterus contracted well, but the patient died an hour later from shock. Histological examination of the uterine muscle in both cases showed that the muscle was quite healthy except for a few small areas which had apparently been cut off by haemorrhage; the fibres stained badly and the nuclei were indistinct. The myometrium was infiltrated with blood and the extravasation was most marked at the inner and outer surface. There was no evidence of permeation through the uterine wall, as would have been the case if the blood had spread outwards from the cavity of the uterus. Thrombosed vessels were to be seen. In the first case leucocytes were present under the retroplacental haemorrhage and around some of the vessels. They were apparently phagocytic rather than inflammatory in origin. A third specimen had also been examined, which was removed from a woman who died shortly after an ordinary ante-partum haemorrhage. Naked-eye haemorrhages could easily be seen on the surface and in the muscle. The histological appearance was identical with the other specimens, except that it was possible to demonstrate the actual rupture of a vein. This appeared to show that there was serious obstruction to the venous flow of a mechanical type. The whole picture of the uteri, both to the naked eye and histologically, suggested the occlusion of the large vessels rather than a permeation of the blood through them as a result of damage to their endothelial lining. Young had noted the same fact, and postulated an intravascular clotting from some unknown cause. Morse had explained the appearance of the uterus upon a theory of torsion of the whole uterus; and Pollock and others had noted extreme torsion of the uterus from left to right. Torsion of myomatous uteri was well known to occur, so that there was nothing impossible in a theory of torsion of the pregnant uterus. The greatest difficulty in accepting this explanation was the frequency of albuminuria at the time of haemorrhage. There was no sufficient evidence that albuminuria often preceded accidental haemorrhage, so it could not be casual. The condition was generally considered to

be some sort of manifestation of toxaemia, but if so, it was different, as Whitridge Williams had said, from any of the ordinary types of pregnancy toxaemia. Young had considered the albuminuria to be only the result of the autolysis of the separated placenta, but his theory was as yet unproved. Hofbauer had produced evidence in favour of histamine as the causative factor, and had reproduced the phenomena of concealed accidental haemorrhage in guinea-pigs by causing acute histamine poisoning. The correct treatment was intimately bound up with the condition of the uterine muscle. Hysterectomy was advocated because the muscle was supposed to be diseased, but this had now been proved not to be the case histologically, and, clinically, it was well recognized that it had not lost its contractile powers, and further, that repeated pregnancies were possible and safe. Apart from exceptional cases there was, therefore, no justification for Caesarean section in these cases. Gibbon FitzGibbon had sometimes treated concealed accidental haemorrhage with success by palliative measures, and this appeared to be as rational as it was irrational to operate upon a woman in profound shock without any clearly defined reason, as had been done in the past.

Professor FLETCHER SHAW (Manchester) said that Dr. King had quoted the figures of a number of maternity hospitals, which showed that albuminuria only occurred in about 30 per cent. of the cases of accidental haemorrhage, and had cited Whitridge Williams as giving the figure at 26 per cent. Professor Shaw disagreed with these figures, and thought the mistake arose from the difficulty in making a diagnosis of accidental haemorrhage. When a patient, far advanced in pregnancy, was brought into a maternity hospital suffering from haemorrhage the diagnosis of placenta praevia was made if the placenta could be felt, and in other cases the diagnosis of accidental haemorrhage was made. These cases of accidental haemorrhage thus diagnosed fell into two main clinical groups; in one the symptoms were comparatively slight, especially the symptom of shock, and this group contained the great bulk of these patients; he felt sure the large majority of these were really instances of marginal placenta praevia. The treatment of these cases was very simple, as practically all the patients recovered if the membranes were ruptured and ergot or pituitrin was administered, or the vagina was tightly packed, as was done in the Dublin school. The other clinical group contained a comparatively small number of cases, but here the patient suffered severely from shock and signs of haemorrhage. These were the patients in whom treatment was not always satisfactory. They were definitely cases of accidental haemorrhage, and in his experience every one of them had albuminuria. It was quite possible that there might be some other factor with the toxaemia as a causative agent of the condition, but he felt sure the toxaemia was always present. As another proof that the condition was due to a general cause such as a toxaemia, he mentioned the fact that in all these severe cases there were large haematomata formed outside the uterus, therefore the condition must be looked upon as a general one and not as a mere local cause affecting the uterus alone. Severe accidental haemorrhage constituted one of the most serious groups of cases met with in obstetrical practice, and there was always a high mortality. If the vagina was packed or the membranes ruptured, and pituitrin or ergot administered, a few of these patients failed to respond, and either died of haemorrhage before the child was born, or, if the uterus was emptied, from post-partum haemorrhage soon afterwards. There were very few of these severe cases, but he felt, when they occurred, that the best treatment was Caesarean section followed by hysterectomy. He himself had treated six in a period of three years during the war, and had saved half of them, but he had never met a single one since that time in which he felt called upon to perform abdominal section.

Dr. J. E. STACEY (Sheffield) submitted figures on ante-partum haemorrhage, and concluded that in both accidental haemorrhage and placenta praevia the cause was toxaemia.

The PRESIDENT considered that the treatment should be palliative in every case.

CAUSES OF DYSTOCIA.

At a meeting of the Midland Obstetrical and Gynaecological Society at the Derbyshire Royal Infirmary, on December 14th, 1926, Mr. FURNEAUX JORDAN (Birmingham), the President, in the chair, Dr. C. D. LOCHRANE (Derby) reported two cases of dystocia. Dr. Lochrane said that in his first case the dystocia was due to a large placenta, and the clinical details were as follows.

The patient was an 8-para; all children were full time and healthy, and there had been no miscarriages. On June 1st, 1925, Dr. Lochrane found the head of the foetus born, but the trunk could not be delivered on account of a firm irregular mass obstructing the upper half of the pelvis. Previously there had been a slight ante-partum haemorrhage, and, although the pains had been strong, the head had only descended to its present position after this mass had been pushed aside. As moderate traction failed to achieve progress in delivery, the patient was deeply anaesthetized with chloroform and morphine, and after considerable difficulty the mass was pushed up and manipulated above the brim of the pelvis. This allowed the shoulders and the remainder of a well developed 10 lb. foetus to be delivered without great difficulty. The foetus showed no oedema or other external abnormality. Half an hour later a huge, thick, solid placenta, not markedly oedematous, but weighing 3 lb. 3 oz., was delivered. Microscopically the placental tissue was found to be unduly dense; no spirochaetes were found.

Dr. Lochrane said that dystocia from this cause must be very rare; he personally had never heard of another case. The clinical and pathological picture did not support the view that oedema from albuminuria was a predominating factor in the production of this huge organ, and there was no suggestion of syphilis, although unfortunately a Wassermann test had not been performed.

Dr. Lochrane also reported a case of dystocia due to sacculation of the gravid uterus, with the following clinical details.

A primipara, aged 23, was admitted to the Derbyshire Hospital for Women on March 7th, 1926, with a history of having been in labour forty hours. Her temperature was 98.6°; her pulse 86, and her general condition was good. Examination showed the uterus unduly prominent, and in a state approaching a tonic contraction; the presentation was a breech, and the rate of the foetal heart was 114. By vaginal examination the os was found to be of two fingerbreadths and displaced upwards; a cystic mass the size of a Jaffa orange, and continuous with the uterus, occupied the pouch of Douglas. An alternative diagnosis of a soft fibroid of the lower pole of the uterus or a non-pregnant horn of a bicornuate uterus obstructing labour was made. At the Caesarean section, performed immediately, the lower uterine segment was found stretched over the lower pole of the foetus, which, being removed, allowed the elevation of the uterus, including the intra-pelvic portion. This latter was non-adherent, and easily released, being held down by a prominent sacral promontory. The appearance of the uterus at this stage was bicornuate; the left cornua, which contained the placenta, was found to be the portion of the uterus which was incarcerated in the pelvis. After manipulating the organ to secure good contraction, the dividing ridge gradually disappeared and all trace of the bicornuate appearance was lost before the abdomen was closed.

Dr. Lochrane remarked that in this case it was the rather less distensible part of the uterine wall comprising the site of placental attachment which had been incarcerated or sacculated. Without being able to give any figures, he was under the impression that a similar observation had been made by others, and this suggested one possible explanation of this form of partial incarceration of the uterus.

Vesico-vaginal Fistula.

Dr. LAVELLE (Derby) described a case of rupture of the bladder followed by a vesico-vaginal fistula.

The patient, aged 34, a 2-para of thirty-two weeks' gestation, was admitted to hospital on December 31st, 1925, following an unsuccessful delivery with forceps. Examination revealed a laceration of the vaginal walls with evidence of injury to the bladder, as 2 oz. of blood were drawn off by catheter. A large hydrocephalic head, partly fixed in the brim, was felt, and the foetus was easily delivered after craniotomy. Following the operation the patient suffered from incontinence of urine, diarrhoea, and signs of lower abdominal peritonitis, accompanied by a pelvic swelling. The temperature remained normal until the seventeenth day after admission. On the twenty-first day the swelling, which then reached to the level of the umbilicus, disappeared after the discharge of 4 to 5 pints of foul-smelling pus per vaginam. Except for incontinence of urine the patient made an uninterrupted recovery. She was readmitted in November, when a vesico-vaginal fistula, 3/4 in. from the cervix, was closed.

Dr. Lavelle said that the abdominal swelling was undoubtedly due to an extraperitoneal extravasation of urine, and it was interesting that this should occur in the presence

of a vesico-vaginal opening. He thought that the fistula dated from the sudden discharge of pus, and that the incontinence previous to this was due to sphincteric failure.

Inversion of the Uterus.

Dr. LAVELLE also described a case of inversion of the uterus.

A woman, aged 31, was admitted to hospital on August 15th, 1926, thirty-seven hours after delivery, with a complete inversion of the uterus. In the one previous pregnancy twins had been associated with albuminuria and an adherent placenta. In the present labour the first and second stages had been normal; in the third stage the placenta was found adherent, and was manually removed. Under light chloroform anaesthesia an attempt was made to reduce the inversion, but this was discontinued owing to the poor condition of the patient. For this cause no further attempt at reduction was made until August 18th—four and a half days after delivery—when, under morphine and deep chloroform anaesthesia, the uterus was replaced after fifty minutes' hard work. The uterus and vagina were packed with gauze, which was removed after eight hours. The convalescence was uneventful.

JAMES MACKENZIE INSTITUTE.

AT the James Mackenzie Institute for Clinical Research, St. Andrews, on December 7th, 1926, Professor G. LOVELL GULLAND gave a lecture on high blood pressure, albuminuria, and glycosuria in relation to life insurance. He said that the general rule nowadays was for the blood pressure to be determined in all proposers over 50 years of age. Discussing the variations of the blood pressure possible within normal limits, he gave as a guiding principle that any pressure above 150 should be regarded with suspicion, bearing in mind the fact that excitement alone might cause a rise of 20 to 30 mm. over the true reading. He thought that albuminuria should always be regarded as a sign of possible kidney mischief, and quoted instances in which an albuminuria apparently utterly unimportant had terminated in a definite nephritis. He next reviewed adolescent albuminuria and emphasized the importance of examining the urine passed first thing in the morning. If this was free from albumin he considered it, as a general rule, safe to pass the candidates. He doubted the value of renal efficiency tests in these cases and in mild nephritics. With regard to glycosuria he stated that even the symptomless type of glycosuria occurring in older people was not a safe risk to accept, since such persons might develop the severe variety. He emphasized the importance of repeated tests, in a proportion of which sugar might be absent. These might, however, be pre-diabetic cases and should have a heavy load added, the only sure method of excluding renal glycosuria and lag curve cases being by means of a full blood sugar curve.

On December 14th Professor MURRAY LYON reviewed the factors concerned in the study of blood pressure—namely, the heart, vessels, blood fluid, and gravity. He showed how the blood pressure might be altered by the viscosity of the blood and by the ever-changing capillary areas, under the influence of posture, mental excitement, muscular effort, and digestion. These results also varied according to the degree of acceleration or otherwise of the heart beat. The question of unduly low blood pressure was next discussed, and he instanced cases of histamine poisoning with peripheral dilatation and loss of blood fluid, thus giving a clue to treatment, which was to raise the blood volume by transfusion with sugar, saline, or gum solution. Apart from the vascular and renal causes of pathologically high blood pressure, Professor Murray Lyon pointed out that a high blood pressure might coexist with a failing heart. He put the question whether it was advisable to attempt to reduce a high pressure, and answered it by stating that probably an attempt should be made in most cases, and the continuance or otherwise of the treatment judged by results. Dealing next with treatment, he emphasized the importance of rest—physical and mental—as complete as possible, but in the overstout and flabby the value of graduated exercise was not to be overlooked. In regard to diet, the danger seemed to lie not so much in an excess of protein as in overeating generally. A salt-poor or salt-free diet appeared useful in some cases. The lecturer drew attention to the benefit to be gained from a revival of venesection, and to the influence of drugs, especially potassium iodide.

Reviews.

ATLAS OF DERMOCHROMES.

Jacobi's Dermochromes[1] is a work which has been well known to the profession in this country since the late Dr. Pringle published it with an English translation in 1904. The success was such that three editions (all now, however, long out of print) were [illegible]ed. The two handsome volumes now [illegible] nominally a fourth edition, really constitute an entirely new work. This we owe to Dr. HENRY MACCORMAC, who has written a completely new text, has rearranged all the old plates, and has been able to add about forty fresh ones, mostly from the collection of Dr. Zieler. It will be remembered that the plates are taken, not direct from the patient, but are made through the intermediary of wax models, which, where practicable, are prepared from casts of the patient and coloured as accurately as possible. There is no doubt that the results as seen in these pages are extraordinarily good, and are far more lifelike than those produced by any direct photographic process of which we have seen examples. They easily pass the practical test which *so few of the illustrations in dermatological textbooks* can pass—namely, that the diagnosis of the condition depicted can be made without reference to the legend beneath the plate. No doubt this is mostly due to the technical skill with which the work has been done, but the effect is aided by the fact that in the preparation of the wax model accidental features on the skin, such as odd moles, freckles, or other blemishes can be eliminated, and thus there is nothing to detract from the unsullied presentation of the clinical characteristics of the disease illustrated. The result is a collection of plates which must be of very real use in familiarizing the student and practitioner with the appearances of the commoner diseases of the skin, and for those whose opportunities of visiting large clinics are limited a study of these plates will provide the next best thing. About a quarter of the plates are devoted to the various cutaneous manifestations of syphilis, which might possibly be considered an excessive allowance for a single disease; but having regard to its gravity, and to the great importance of making a correct differential diagnosis between it and other dermatoses, the proportion cannot be regarded as unreasonable. It is hardly necessary to remind our readers of the power of syphilis to imitate, sometimes with uncanny plausibility, skin lesions due to other causes. On the whole, this collection of plates is a very fairly complete series of illustrations of the more important dermatoses. Few conditions of any significance are unrepresented, but there might with advantage be another illustration of rosacea, laying more stress on the erythematous rather than on the pustular form of the disease. The collection would also be more complete if room were found for examples of Schamberg's disease, which, after all, is not so very uncommon, and of exfoliative dermatitis. Possibly this last has been omitted owing to the difficulty of demonstrating its characteristics on the limited area which is capable of reproduction by means of a wax cast.

A few words only need be said of the new text written by Dr. MacCormac, though it must be regarded as not less essential than the plates, which without it would lose a great deal of their value. Dr. MacCormac has made the text a much more important feature than it was in the original Jacobi. He has not been content with a bare explanation of the plates, but has provided a concise account of each disease illustrated, including its etiology and differential diagnosis and something of its pathology. Nor has he forgotten to give good directions for *treatment*, in which the most modern methods are included, at least so far as they have stood the test of practice. In short, he has provided a complete textbook of dermatology, from which the only omissions are subjects still matters of controversy and theoretical discussions in general.

In conclusion, we must congratulate both the author and the publishers on the production of a magnificent work,

[1] *Jacobi's Atlas of Dermochromes.* Fourth edition, with entirely new and original text. By Henry MacCormac, C.B.E., M.D., F.R.C.P. In two volumes. London: W. Heinemann. 1926. (Imp. 8vo, pp. x + 100; 147 figures, 79 plates. £5 5s. the two volumes.)

which we feel sure will prove a great success. In view of the large number of coloured plates and the expense necessarily entailed in their preparation, the price charged, although high, cannot be considered excessive.

PROBLEMS OF LOCAL GOVERNMENT.

During recent years an increasing interest has been taken by the medical profession in matters of local administration, and medical men and women have been urged to become members of local government authorities. To those who contemplate following this advice, as well as to those who have already had experience in this sphere, Mr. E. D. Simon's book *A City Council from Within*[2] will be welcome. As Professor Graham Wallas says in his preface to the volume, "For the average citizen the possibility of health, of happiness, of progress towards the old Greek ideal of 'beautiful goodness' depends on his local government more than on any other factor in his environment; and yet the books which record and analyse English experience and invention in the sphere of local government are amazingly few and uninforming."

Mr. E. D. Simon is known to many as having succeeded Dr. T. Watts as member of Parliament for the Withington Division of Manchester in 1923, and as having been, in turn, defeated by him at the last general election. Mr. Simon is an ex-Lord Mayor of Manchester and is a recognized authority on housing and other questions. His experience amply qualifies him for expounding matters of municipal administration, and he does this in an interesting, effective, and informative way. Local administration in a county borough is free from some of the complications which arise in the work of a county council or of the council of a non-county borough or urban district. The latter, therefore, are not dealt with in this volume, though the question of the most suitable area for local government purposes receives some notice. The earlier chapters describe the work of the five most important committees of the city council—electricity, public health, housing, education, and finance. Mr. Simon was chairman of the housing committee, and his description of its work and difficulties is full; his chapter on the finance committee, too, may be described as adequate for his purpose. To apply either of these adjectives, however, to the chapters dealing with the other committees could scarcely be appropriate. That on the education committee is singularly meagre, and several aspects of the work of the public health committee are only perfunctorily referred to. The maternity and child welfare work which is commonly placed under an independent committee is, in Manchester, wisely given to a subcommittee of the public health committee; but no mention is made of mental disease or mental deficiency, no doubt because these are in the sphere of other independent committees.

The main and real value of Mr. Simon's book lies in the admirable way in which he sets out most of the chief problems relating to the machinery of urban administration which still remain for solution. These problems are not fully discussed, but they are clearly posed, the most important considerations bearing upon them are excellently stated, and an indication is usually given as to the solution which the writer's experience would lead him to favour. Such problems are: the value of properly selected co-optative members on committees, the methods of securing the co-ordination of the work of the various committees and its control by the council, the extent to which and the methods by which a Government department should interfere with the work of a local authority, the way in which a municipal civil service should be recruited and individual members thereof promoted or interchanged, the possible separation of the technical from the administrative functions of the principal officers and the relation of the town clerk to his colleagues, the proper salaries for these principal officers, and the multiplicity of the duties of a lord mayor or mayor and the arrangements for their more effective performance. It will be noted with satisfaction that Mr. Simon is quite emphatic in his opinion that the appointment of co-optative members, carefully chosen, is of the utmost value and should be extended; and that "the maintenance and improvement of the salaries of the head officials is the most important item in the successful carrying on of local government." He says in this connexion, "The fact that the salaries of head officials are now on the low side, and still more the fact that they are discussed in public every time an increase is suggested, is in my view the most disturbing and dangerous aspect of local government. . . . A lowering of the status and salaries of the head officials might easily lead to incompetence, corruption, and the decay of local government."

A perusal of Mr. Simon's book reinforces the opinion quoted above from Professor Graham Wallas's preface, and should lead to a greater appreciation, by the medical profession as by others, of the importance and attraction of the spheres of work with which it deals. It may lead us in our time to repeat the declaration of Pericles in Athens, "We differ from other States in regarding the man who holds aloof from public life not as quiet, but as useless."

CRIPPLED AND INVALID CHILDREN.

The Invalid Children's Aid Association has published a small volume with the title *The Care of Invalid and Crippled Children in School.*[3] It is founded on notes put together by Mr. R. C. Elmslie and Dr. Letitia Fairfield for lectures originally delivered to the school nurses attached to the London County Council's schools for physically defective children. In his introduction Mr. Elmslie says it is hoped that this extension and elaboration of the notes may interest and instruct non-medical workers in schools and clinics for cripples all over the country. The otherwise excellent account given of the history of the establishment of schools for physically defective children omits any reference to the school started in the wards of the Royal National Orthopaedic Hospital by Mrs. Muirhead Little, which was the first attempt, at any rate in London, to cope with the problem of the education of crippled in-patients. Responsibility for this school was afterwards assumed by the committee of the hospital until it was taken over by the educational authority of the London County Council. Events have moved fast since, in 1919, the Central Committee for the Care of Cripples was established under the chairmanship of Sir Robert Jones. Working with the Invalid Children's Aid Association the committee has already done much, and the county organization, first adopted in Shropshire, and then in the Oxfordshire county group, as described by Mr. Girdlestone, has been copied in many counties, and will soon become general. In the great cities the work must be done in schools for the physically defective and in the orthopaedic departments of the general hospitals, where special hospitals do not exist. Official recognition has not been tardy. In 1925 the Board of Education practically adopted the scheme of the committee officially. It is already the duty of the local health authorities to provide treatment for all cases of tuberculous disease, and on the first day of this year it became the duty of the education authorities to provide education for all crippled children; thus the provinces will be brought into line with London and some other places which have already grappled with the problem.

Mr. Elmslie's article on tuberculous disease in general, and his descriptions of its particular localizations, as well as of other joint affections and crippling diseases, should be of great use to the voluntary workers in all schemes for the care of cripples. Dr. Letitia Fairfield, in small space, has well outlined the problems connected with heart disease and rheumatism in children. Of the report of the subcommittee of the British Medical Association, which appeared in the Supplement of July 3rd, 1926, she says that it contains the best available summary of present knowledge of rheumatism in children. The short chapters she has written on the structure and function of the heart in health and disease, on diseases of the heart, on the prevention and treatment of rheumatism and its sequelae,

[3] *The Care of Invalid and Crippled Children in School.* By R. C. Elmslie, O.B.E., M.S., F.R.C.S., and Letitia Fairfield, C.B.E., M.D., D.P.H. London: The Invalid Children's Aid Association. 1926. (4¾ × 7, pp. 95; 8 figures. 1s.)

and on chorea, are clearly and simply expressed; and should be of value to those for whom the pamphlet is intended, but we do not think that the illustrations which represent the heart opened to show its chambers and a diagram of the circulation can convey any useful ideas to persons who have no other knowledge of practical anatomy and physiology. On the other hand, they are not likely to do harm as long as her readers realize their own ignorance. The twelve practical hints provided by Dr. Letitia Fairfield are probably the most valuable part of the pamphlet, and if understood and taken to heart by Red Cross nurses and other welfare workers should be of the greatest use and benefit to the cripples who come under their care.

DISEASES OF THE THORACIC AND ABDOMINAL AORTA.

As the first part and the arch of the aorta have monopolized attention rather to the exclusion of the rest of the largest artery in the body, Drs. CH. LAUBRY, A. MOUGEOT, and J. WALSER's work *Les Syndromes d'Aortite postéricure (Aortite thoracique, Aortite abdominale)*[4] is a valuable contribution to the redressing of the balance. Apart from aneurysm, which, of course, has been amply described, the clinical manifestations of the well established changes in the thoracic and abdominal aorta have, from their inaccessible position, remained almost a closed book; Huchard, indeed, spoke of the thoracic aorta as the latent zone. A summary of the morbid anatomy of simple atheromatous aortitis, of simple syphilitic aortitis, and of syphilitic aneurysm is illustrated by three coloured plates. The peri-aortic lesions, and the reactions in the adjacent tissues, such as mediastinitis and neuritis, are mentioned. The symptoms, as was to be expected, vary according as to whether the thoracic, the abdominal, or the diaphragmatic region of the aorta is mainly or exclusively affected. In the chapter on physio-pathology the complicated clinical picture is elucidated by the application of Marey's estimation of the rate of propagation of the pulse wave (V.P.O.P.=vitesse de propagation de l'onde pulsatile), which is held to be an index of the elasticity of the arterial wall and so also of aortitis.

Although symptoms due to disease of the aorta vary according to the situation of the disease, pain is present in all instances; it is often the earliest symptom, and is characterized by its fixity, intensity, and duration. When the thoracic region is affected the pain is mainly on the left side of the chest, but it may radiate to the arm and occipital region; in aortitis about the diaphragm the pain is situated in the epigastrium and the loins, and disease of the abdominal aorta causes angina abdominis, which, like angina pectoris, may be brought on by exertion. Dyspnoea of varying character is common and has been explained in various ways, but probably peri-aortitis and mediastinitis are more important than mechanical pressure. Dysphonia and dysphagia may also occur. The physical signs, and the radiological and other evidence are considered, and an analysis of the various clinical syndromes is given, including symptom-groups due to involvement of the branches of the abdominal aorta.

In conclusion we may say that this is a valuable monograph on a subject of some difficulty.

PERNICIOUS ANAEMIA.

DR. F. A. EVAN's book on *Pernicious Anemia*[5] is based on experience at the Johns Hopkins Hospital and on a survey of literature, which, however, is rather strikingly devoid of reference to the recent work of Hurst and others, possibly because it has been published in the *Guy's Hospital Reports*, where it has been somewhat buried. Dr. Evans's presentation of this much discussed form of anaemia is extremely broad-minded, the arguments for and against different views being fairly stated, and his conclusions being drawn with caution. The statistics of the Johns Hopkins Hospital from its opening up to the end of 1922 do not lend any support to the prevalent impression that Addisonian anaemia has become commoner, and its occurrence in children appears extremely doubtful. He also points out that though it undoubtedly occurs in the elderly, some of its outstanding features, such as achylia gastrica, a sallow complexion, anisocytosis, and leucopenia, may be present at an advanced age without the complete symptoms, and that therefore the diagnosis must be accepted with reserve.

In the chapter on etiology is a valuable discussion on the part played by the spleen and by cholesterol; the observations of Clark and the author on the latter subject are mentioned, and it is suggested that some haemolysin, normal or abnormal, unites with the lecithin of the cells, and, when the cholesterol content of the plasma is low, as it markedly is in pernicious anaemia, destroys them. In this connexion it is significant that the tissues richest in lecithin are the envelopes of the erythrocytes and the nerve sheaths, and that the outstanding features of the disease are haemolytic anaemia and subacute combined degeneration of the spinal cord.

The clinical characters are fully described, and it is stated that the experience at the Johns Hopkins Hospital is not in agreement with the contention that the eosinophilia occasionally seen indicates a mild stage of the disease. The blood picture in tertiary syphilis may be that of pernicious anaemia, but as a rule achylia gastrica is not present. Dr. Evans believes that the anaemia due to *Dibothriocephalus lata* is regarded as identical with pernicious anaemia only because the observations relied on were made before the complete clinical picture was satisfactorily defined.

As regards treatment, most reliance is placed on simple supporting measures, and a high protein diet is recognized as being sometimes of value; arsenic is a general tonic and a haematopoietic stimulant, but if pushed to excess may be a haematopoietic poison. Dilute hydrochloric acid is recommended in all cases, and blood transfusion is fully and philosophically discussed. The attractive notion of giving cholesterol cannot be recommended at present.

COMMUNISM.

WE ventured recently to suggest that the advocacy of a system of official vocational selection was tantamount to proposing the adoption of one of the tenets of communism. Probably no word is nowadays more frequently on the lips of men than communism; yet to most minds the only idea it conveys is of something to be regarded with fear or hatred. It would be well that people should clear their minds on the subject by reading Mr. AL. CARTHILL's book *False Dawn*.[6] Mr. Carthill sets forth to inquire what are the causes which render society susceptible to revolutionary ideas, being convinced that communism is the sixth in a chain of ideas which have led to crises in the history of man, at all events of European man. Thus the idea of the Great State to replace the city state came into Europe in the fourth century B.C. with the Macedonian conquests. Then came Christianity to teach the brotherhood of man. The Reformation followed with its destiny of destroying religious sanctions and making the State supreme. The fourth great idea, Liberalism, levelled all orders in the State and destroyed the power of any citizen to resist the State's commands, though it left intact the privilege of wealth. Nationalism, the fifth idea, had the intention of making the population more homogeneous and more inclined to follow a common policy by eliminating alien and possibly hostile elements. It is possible, says Mr. Carthill, to regard communism as the ultimate goal of man to which the history of the five other ideas naturally leads.

The two propositions upon which communism is based are: first, that labour, and labour only, produces value; and secondly, that both justice and expediency require that those only who have produced should enjoy the product. In themselves raw materials have no actual but merely potential values. It is the application of labour to raw materials which creates values. To the community belong

[4] *Les Syndromes d'Aortite postérieure (Aortite thoracique, Aortite abdominale)*. Par Ch. Laubry, A. Mougeot, et J. Walser. Bibliothèque des grands syndromes. Paris: Octave Doin. 1925. (Med. 8vo, pp. 234; 19 figures, 7 plates. 25 fr.)

[5] *Pernicious Anemia*. By Frank A. Evans, M.D. London: Baillière, Tindall and Cox. 1926. (Extra post 8vo, pp. 178. 11s. 6d. net.)

[6] *False Dawn*. By Al. Carthill. Edinburgh and London: William Blackwood and Sons. 1926. (Demy 8vo, pp. 224. 10s. 6d. net.)

hs of right all raw materials; the community can apply the labour of its members to creating from raw materials the commodities it needs; and it is for the community to say how the products are to be divided. Communism, therefore, requires from all members of the community sacrifice, voluntary or compelled, and a total subordination of private to public interests. The artisan has no more right to his tools than the king to his crown or the usurer to his hoard. On to such a doctrine as this are naturally hung the abolition of all rent and interest; the banning of private property; eugenic selection for propagating the species; limitation of families; euthanasia for old, useless, or mentally degenerate persons; coercion in cases of strike or mutiny; and the abolition of religion, since the only God is man, the only Church the community, and the only sin disobedience. Mr. Carthill agrees that the two propositions of communism are questioned, and that quite possibly an erroneous meaning has been attached to the word "values." Nevertheless, the idea has appealed to clever men, and especially to the scorned and injured intellectual. The acceptance of the propositions is an act of faith; the truth of the creeds depends very largely on the truth of the doctrine of the perfectibility of man—a doctrine which is, Mr. Carthill admits, to say the least of it, extremely dubious. This does not prevent people believing in it. And the conjunction of impatient idealism with actual, grievous, and unredressed suffering begets revolutions.

The leaders in revolutionary ideas are generally men of a superior class. Omitting those eager for plunder, the frondeurs, the cranks, and temperamental traitors, Mr. Carthill thinks that the leaders are usually drawn from among compassionate and sentimental members of the intelligentsia, supported to some extent by economists and evolutionists. Struck by the waste and injustice apparent all around them, and gifted with intelligence, though without much intellect, these impatient idealists deduce that things cannot be left to themselves much longer, and that as evolution does not do what they want, revolution should be tried instead. The author traces the development and extension to the masses of this attitude, and sums up by asserting that society, as at present constituted, is oppressive, unjust, and wasteful. Evolution alone is not leading to betterment. Palliatives do not cure. Communism has promised a healing reformation. But communism can only be realized by means of a gradual change in the character of man. In the meantime impatient idealists may attempt to find a remedy in revolution. But revolutionary teaching only aggravates the ills, and removes still further the possibility of realizing the communistic idea. We are left, therefore, by Mr. Carthill without any concrete proposals, except that he would like to see a league of youth to resist not communism but subversivism.

NOTES ON BOOKS.

THE fourth edition of Miss GOODALL-COPESTAKE'S *Theory and Practice of Massage*,[7] of which the first edition appeared more than eight years ago (see JOURNAL, April 13th, 1918, p. 480), has been brought up to date by the addition of paragraphs on sacro-sciatic strain, myositis ossificans, and encephalitis lethargica and their treatment by massage. Additional illustrations have been included and the list of examination questions increased. The work, which is now regarded as a standard textbook on massage, needs no further recommendation from us.

The little work entitled *Scourges of To-day*,[8] by Dr. E. T. BURKE, which forms the latest contribution to the series of "Modern Health Books" edited by Professor D. Fraser Harris, contains all that the intelligent layman need know about venereal disease, cancer, tuberculosis, and alcoholism. Apart from the erroneous statement that chancroids are only situated on the genital organs, the teaching is sound and clear, and the work is admirably suited for the class of readers for whom it is intended.

[7] *The Theory and Practice of Massage.* By Beatrice M. Goodall-Copestake. Fourth edition. London: H. K. Lewis and Co., Ltd. 1926. (Demy 8vo, pp. xx + 267; 72 figures, 22 plates. 12s. 6d. net.)

[8] *Scourges of To-day.* By E. T. Burke, D.S.O., M.B., Ch.B.Glas. The Modern Health Books. London: Faber and Gwyer, Ltd. 1926. (Fcap. 8vo, pp. xiii + 166. 3s. 6d. net.)

Mr. VLASTO has apparently exercised less care in the selection of the title for his book on *Nursing of Diseases of the Nose, Ear, and Throat*[9] than in the compilation of the well written and helpful text. At any rate, he has missed the opportunity of emphasizing in the title the fact that patients rather than diseases are the primary objects of the nurse's care and attention. The scope of the book, the selection of illustrations—many of which are of instruments commonly used in special practice—and the breezy style of the author, who served in the Royal Navy with credit during the war, together make up a little volume for which many a probationer will be thankful, especially if she happens to read his opening apologia early in her professional career. Those who teach nurses may also find it of assistance in the preparation of lectures. In another edition the author should say a little more about the care of patients after major operations on the pharynx and larynx, especially tracheotomy. The various methods of treating the wounds resulting from mastoid operations deserve fuller mention, and a picture of a properly applied mastoid bandage might well find a place.

There is something overwhelming in the thoroughness of the American when he gets hold of an idea. Dr. SANFORD BLUM of San Francisco thought that the dietaries he had prescribed for the last twenty years might be of use to others; so he wrote a book, *Practical Dietetics for Adults and Children in Health and Disease*,[10] now in its second edition. The practitioner wants a diet, let us say for anaemia, and Dr. Blum provides him with a diet-sheet suitable for a society woman suffering from repeated dietetic errors, a business woman, a girl of 18 who has lived in the tropics, or a bank clerk who cannot tolerate milk. It is all very clearly arranged, with neat general suggestions at the foot of each diet. The English practitioner may find some difficulty in getting his patients to provide themselves with squabs, egg plants, graham crackers, and squash; but there should be no difficulty in carrying out a recommendation to avoid waffles, corn, and clams. We notice that most patients are requested to abstain from "alcoholics"; a wise request, perhaps.

The fifty-ninth annual issue of *Whitaker's Almanack*[11] (henceforward to be known as "The Complete Whitaker," to distinguish it from the new abridged edition) has been to a large extent rearranged. A table of abbreviations in common use now follows the index; and among the items of general interest will be found the results of the 1926 census in Northern Ireland, and of those in the Irish Free State, Australia, New Zealand, and the Union of South Africa. "Questions of the Day" are dealt with in fifty-seven short articles, and these are followed by annual summaries of events, a list of notable deaths, notes on meteorology, science, invention, and the arts, a retrospect of sport, and a diary of events for 1927. *Whitaker's Almanack Abridged*[12] is a new book, replacing the popular edition, now no longer issued. It differs from the volume it replaces in many particulars, but principally in containing not merely a part of the complete edition, but an abridgement of the whole, as its name implies. Although this work is smaller than its predecessor the number of entries in the index has not been reduced, and copious cross-references are given.

PREPARATIONS AND APPLIANCES.

Phenyl Cinchoninic Acid (Agotan).

PHENYL cinchoninic acid, or, to give it its full name, 2-phenyl quinoline-4-carboxylic acid, was introduced to the medical profession under the proprietary name of atophan. The drug was included in the *British Pharmaceutical Codex* (1923) under the name quinophan and in the *United States Pharmacopoeia* X (1926) under the name of cinchophen. Messrs. Howards and Sons, Ltd. (Ilford), have put forward a preparation of the drug under the name of "agotan." They claim that their preparation is of a higher standard of purity than that laid down in the *British Pharmaceutical Codex*.

This drug of many aliases has acquired a firm reputation in the treatment of gout and of chronic rheumatic conditions. Its outstanding action is to cause a great increase in the excretion of uric acid, but also it acts like salicylates in reducing the tem- [illegible] ion to its general action, when injected hypodermic- [illegible] of articular or muscular [illegible] preferable mode of local [illegible] cinchoninic acid is rapidly [illegible] profession, as it affords relief in a number of chronic and painful conditions which are very refractory to other methods of treatment.

The Society of British Neurological Surgeons.

THE establishment of a Society of British Neurological Surgeons, with Sir Charles Ballance as President, was announced in our last issue. The occasion is of so much surgical and historical interest that many will be glad to have the opportunity of reading the President's speech and those of the four emeritus honorary members who were present at the inaugural meeting on December 2nd, 1926. Sir Charles Sherrington was unavoidably absent.

REMARKS AND REMINISCENCES.

BY

SIR CHARLES BALLANCE,

PRESIDENT.

THE pageant of surgery and neurology through which I have lived has been the most glorious of all time. As a young man I heard VIRCHOW, HELMHOLTZ, and LUDWIG lecture; I attended the clinics of BERGMANN, THIERSCH, and VOLKMANN; I witnessed PASTEUR and LISTER at work, and I had the great privilege of the friendship of Sir JAMES PAGET. When I entered St. Thomas's Hospital as a student nearly all operations, and they were few in number, were followed by sepsis—suppuration, cellulitis, erysipelas, septicaemia, or pyaemia. It was just before this time that some hospitals on the Continent were closed because hospital gangrene and death followed every operative intervention. The Hôtel-Dieu in Paris, like all other hospitals, became a hotbed of sepsis; and it was remarked that the inscription over its doors, "This is the house of God and the Gate of Heaven," was more literally true than its founders appreciated. The evils of overcrowding—want of air and space, and bad sanitation—made themselves felt; so that on the occasion of a fire it was said, "Let the hospital burn and save the sick!"

Milton's terrible description of a lazar-house was also in large measure still true, especially at some places on the Continent:

> "Despair
> Tended the sick, busiest from couch to couch;
> And over them triumphant Death his dart
> Shook, but delay'd to strike, though oft invok'd
> With vows, as their chief good and final hope."

The place that surgical intervention occupies in the treatment of disease is now quite different, and it would appear that those recently qualified are quite unable to appreciate the marvellous progress during the last fifty years. The change Lister wrought in surgery has been well described by a French surgeon (Le Dentu):

> "By what miracle has the slender seedling full of sap become the vigorous tree beneath the shade of which works our restless activity, ever in search of new triumphs? . . . I am one of the men of a privileged generation. I have known that *deceptive Surgery* with more grave disasters than successes, that *Surgery* in fine, which saw itself reduced to laying down the knife as mortal complications fell with impartial fatality on all the operation cases in a ward."

This striking contrast between that which is and that which was has thrown more and more into the background the conditions under which were passed the earlier days of my medical studies. When I was a dresser at St. Thomas's Hospital all serious suppurating wounds were transferred to No. 8 block of the hospital. This block was presided over by an old nurse with several other nurses under her. This old nurse treated all cases with chlorinated soda poultices and the administration of large doses of brandy and perchloride of iron; the house-surgeon was sent for at night to make incisions. Most of the cases thus treated survived, and when the great war broke out I remembered the value of free chlorine in the treatment of septic wounds. Thus the Carrel-Dakin method of treating wounds was to me and other surgeons of my standing but the revival of an old method with the addition of a novel and striking technique.

When in 1884 I attended surgical clinics in Germany I was invariably asked, not "Do you know Paget?" but "Do you know Lister?" London was very late in accepting and practising the principles of Listerian surgery.

In 1880 I attended a "Brown" lecture by Sir JOHN BURDON-SANDERSON on the tuberculous process. He maintained that, as dust from St. Paul's Cathedral, from Westminster Abbey, and from his own drawing-room when inoculated under the skin of the guinea-pig produced a tuberculous lesion, the disease could not have a specific origin. The following year Koch demonstrated the tubercle bacillus.

In 1884 I joined the first class ever formed in bacteriology in the ancient University of Leipzig. It was held every day for six weeks and was taken by Becker, Koch's chief assistant, attired in full military uniform. The cholera and tetanus bacilli were then known, and each member of the class had to prove Koch's four postulates with regard to the known pathogenic organisms. This was the origin and cause of my work with my friend the late Professor Shattock on the intimate pathology of malignant disease. SHATTOCK was a microscopist of repute, and I was a bacteriologist knowing not less at that time of the subject than anyone else in England. I suppose in some way it became known that I had studied bacteriology, for I was invited to become bacteriologist to the London water companies. My family had been decimated by malignant disease, and when I was a student I had made up my mind to work at the subject, and meeting Shattock on my return from Leipzig we planned together six years' evening work on the intimate pathology of carcinoma.

Some time in the late eighties I became acquainted with the work of THEODORE CASH, Professor of Pharmacology in the University of Aberdeen, by which he proved that the introduction of solution of mercury perchloride into the veins of animals saved them from death after they had become ill from the injection of a fatal dose of a pathogenic organism. During the last few years there have been several papers on the introduction of mercurial salts in solution into the veins, but I have missed all mention of the name of Theodore Cash. The same may be said of "bipp," so extensively and successfully used during the great war. Beck's paste thirty or thirty-five years ago was a similar preparation, and I used it extensively for sinuses and other cases. I met Beck more than once, but when "bipp" appeared everyone seems to have forgotten Beck. It is curious how men and methods in surgery are so soon forgotten, and then unwittingly an old treatment is brought forward as a new thing or a new discovery. A good example is Bier's congestion treatment, which has been practised in Egypt for thousands of years. It is mentioned in the Proverbs "The blueness of a wound cleanseth away evil." It is well to remember the words of Celsus: "Though we should not refuse to give modern authors due credit for their discoveries and happy imitations, it is none the less just to restore to the ancients what properly belongs to them."

I remember being asked by the house-physician in the early nineties to see a case in one of the medical wards at St. Thomas's. After a slight examination I turned to the house-physician and said, "You told me you had a case to show me, but I say this is Risien Russell's monkey." The house-physician replied, "I don't understand what you mean, Sir." I had just been reading Russell and Horsley's paper on the symptoms produced by the removal of the lateral lobe of the cerebellum in the monkey. The cerebellar abscess was successfully opened the same afternoon and the patient recovered.

Besides his pioneer work on the cerebellum RISIEN RUSSELL carried out experiments of great value with reference to the cortical representation of movements of the eyeballs and of the movements of the vocal cords. He was well known as a most successful clinical teacher of neurology.

In 1900 I was appointed assistant surgeon to the National Hospital for the Paralysed and Epileptic, Queen Square. I then came in contact for the first time with two remarkable men, HUGHLINGS JACKSON and FERRIER. I also came to know Bastian, Buzzard, Gowers, Ormerod, Howard Tooth, James Taylor, Aldren Turner, and Purves Stewart. Charles Beevor was an old friend. I do not mention Horsley as we had met previously almost every day for five years at the Brown Institution, and I had been on several occasions on duty at the hospital for him before I was appointed a member of the staff. The example and fascination of the lives of the eminent men who formed the senior staff of the National Hospital when I first had the honour to become a member of that staff lighted a fire of enthusiasm and fruitful research in all those who came under their influence.

BUZZARD had served in the Crimean war and possessed an indefinable quality, difficult to express in words—a certain distinction of manner and mind, which in my experience was possessed by others who had been through that war. I remember operating on a case of cerebellar abscess under his care in a large public-house close to the Thames. The result was that I was invited on the next occasion of the University boat-race to witness it from the roof of the public-house. Refreshments were supplied gratis!

ORMEROD was a most learned physician, and his knowledge of the literature of neurology was encyclopaedic. He was always ready to place at the disposal of others his great stores of learning. He was shy, reserved, and indeed most unwilling to claim for himself credit when it was due.

HOWARD TOOTH had a clear and brilliant intellect. He was a colleague of mine for some time in Malta during the great war. We saw cases together in the hospitals of that island, and I had many opportunities of observing his shrewdness and wisdom in the diagnosis of obscure and difficult cases of injury of the nervous system. In fact, my association with him was of great value to me. Both Ormerod and Tooth possessed charming personalities.

CHARLES BEEVOR was a delightful person. It was good for me to have known him well. He was associated with HORSLEY in much experimental work, and did not get the credit which I think was due to him. I was often an onlooker at these experiments. Horsley would stimulate the cortex or corona radiata, or internal capsule of the brain, and Beevor would call out the movements induced. The recognition of the precise movement induced by excitation of a definite area of the brain requires a mental judgement greater than the performance of the actual operation of stimulation. But no doubt Horsley shared with Beevor the recognition of the muscular movements following electrical excitation of the brain. One of the last researches undertaken by Beevor was on the distribution of the vessels of the brain. It was a splendid and admirable contribution to neurology; but I fancy it is now scarcely known.

ALDREN TURNER was a constant worker, a good friend, a keen physician, and had been fortunate in being associated with Ferrier in some of his experiments.

PURVES STEWART was an indefatigable worker as house-physician. I do not remember ever reading more complete notes of cases than those typed by him. It was while he was house-physician at the National Hospital that he and I did some experiments which were subsequently published under the title of "Healing of nerves." His energy was prodigious. Often to save time he would bicycle in the early morning to the Brown Institution, where the experimental work was done, and return for breakfast.

JAMES TAYLOR was a typical Scotsman and a shrewd and wise physician. I removed from a patient of his a large arachnoid haematocele. In this case there was optic neuritis, mental disturbance, and some contralateral paralysis. These arachnoid cysts were first described by Richard Bright in 1841. In Holmes's *System of Surgery* Sir Prescott Hewitt discusses them. I was familiar with the literature. Especially I had been impressed with a case recorded by Hewitt in the *Lancet* for 1846. A boy, aged 8 years, received a blow on the head from a cricket ball and shortly afterwards showed signs of insanity. He had recurrent attacks of insanity with intervals of health till his death fifteen years after the injury. At the necropsy a large arachnoid cyst was found. The intermittent insanity was probably due to intermittent haemorrhage into the cyst such as we know occurs in some cases of *haematocele of the tunica vaginalis*, thus explaining the slow increase in the size of the tumour.

Dr. BASTIAN was the protagonist of spontaneous generation; he made some friendly attempts to interest me in the subject, but I was so deeply immersed in and enthusiastic over the writings of Pasteur and Lister that I was not really interested, and was wholly sceptical of the value of his experiments.

GOWERS was a difficult man for a junior surgeon to know. He was a fine teacher in the out-patient room, had published two classical volumes on diseases of the central nervous system, and a tract of the spinal cord had been discovered by him. The first case of cerebral tumour I operated on had been under his care in the wards for some months. This boy, about 14 years of age, while in the hospital became an expert thief, stealing from the patients, the nurses, the staff, and even the secretary director. The tumour was a large soft glioma, and the operation consisted in not much more than the performance of a large craniectomy—a decompression, in other words. The central mass of the tumour was very soft, and I shall always remember the enthusiasm with which HENRY HEAD at my request boiled a silver teaspoon so as to enable some of the soft centre of the growth to be ladled out of the head. The result of the operation to the patient was that he obtained great relief from the physical condition from which he suffered and was cured of his moral defect. He lived for about three years after the operation, and during this time he did not steal. Head has done priceless service for neurology, and has ever set before us a standard of unflagging industry, enthusiasm, and zeal for everything he undertook.

The first meningeal spinal cord tumour was removed by Horsley from a patient of Gowers. Dr. Hughlings Jackson and Sir David Ferrier were present. It was said that the pain in this case was so great that the patient's cries could be heard some distance down the street in which he lived. I assisted Horsley at the operation. An interesting anatomical point arose. Three laminae were removed and no tumour was seen, but remembering that the spinal roots come off from the cord higher up than their corresponding vertebrae, two more laminae were taken away, the tumour was exposed, and the operation completed without difficulty.

Horsley and I at first only had a kitchen to operate in at the National Hospital, but, following the Listerian doctrines, I do not think we ever had sepsis supervening on an operation. In those early days very few operations on the nervous system were performed—probably not more than one a month, if so many.

HUGHLINGS JACKSON remains in our vision as the Socrates and Lycidas of neurology. Independent of Jackson's mental eminence and philosophic mind, his attendance at Moorfields Eye Hospital in early life was of supreme importance to the future progress of neurology. When I first met him he was always asking me questions which I could not answer, which disturbed me not a little; but I soon found that they were not put to confuse me but to gain information. He contributed four papers on "Defects of sight in diseases of the nervous system" during 1863, 1865, and 1866. These papers are of extraordinary interest. They illustrate the slow unravelling of the truth with regard to the nature and cause of the optic neuritis of intracranial origin. Jackson described the association of headache, vomiting, and optic neuritis in cases of cerebral tumour, and laid great stress on the fact that when amaurosis results from disease of the brain the chief

lesion is but rarely situated in the optic nervous system. In 1865 Jackson wrote:

"It occurred to me there might be particular parts of the hemisphere disease of which produced amaurosis; just as disease of a particular part of the left hemisphere produces aphasia. I was [he says] at one time *sliding* into the belief that disease of the right hemisphere was very important from the point of view of optic neuritis; but I received a *check* in Case xii which prevented me sliding into that conclusion."

In another place the sentence occurs, "I suggest that unilateral convulsions point to disease of the opposite parts of the brain." This is interesting, for I remember when unilateral paralysis and unilateral convulsions were not linked together in the mind as being likely to be caused by the same disease on the opposite side of the brain; indeed, at that time convulsions and paresis seemed to be thought of without any relation to each other. The Hippocratic insight and wisdom shown in Jackson's papers on epilepsy, speech, and the diagnosis of brain tumour form for him an enduring monument.

I do not think that a decompression operation was directly performed for the relief of optic neuritis before 1890. The subsidence of the neuritis following operation for brain tumour had been noted, and this is how it came about that an operation was performed in some cases when the locality of the tumour could not be diagnosed simply for the relief of the swelling of the optic disc. It was James Taylor who contributed the first paper on "optic neuritis in its relation to intracranial tumour and trephining" (*Ophthal. Soc. Trans.*, Vol. XIV), though in the previous year (1893) Horsley had noted the subsidence of optic neuritis after trephining. From the date of James Taylor's paper decompression became a recognized operation for the relief of choked disc or optic neuritis and to prevent the onset of optic atrophy and blindness. In this relation mention must be made of MARCUS GUNN, whose accurate measurement of the swelling of the optic disc, phenomenal in those early days, was of the greatest value. It was said that a description by him of the retina in disease was equalled only by the description of a visible flower bed with its flowers and weeds of varying size and colour.

The passage in Hippocrates (Littré's translation, vol. ix, p. 159) in which craniectomy is recommended as a cure for blindness without evident disease of the eye seems as if Hippocrates operated for the relief of optic neuritis. "When sight fails without evident disease of the eyes an incision should be made in the parietal region, the bone trephined and the fluid beneath let out—that is the treatment, and thus these patients get well." The seed dropped by Hippocrates did not germinate in regard to the treatment of amaurosis without visible ocular disease till some forty years ago.

The craniectomies performed at the present day are not greatly, if at all, in advance of those carried out by the Hippocratic surgeons. It seems to me that with the present knowledge of physics and mechanics a time must come when the contents of the skull will be as quickly and as easily exposed as the contents of the abdominal cavity are by incision of the abdominal wall; indeed, I look forward to a future when a window in the skull will be made by the surgeon with the like gentleness, precision, and ease that a pane of glass is fashioned by the glazier by means of a diamond.

Decompression, as we all know, is not effectual without incision of the dura. An investigation by Sherrington and myself many years ago showed that even after the performance of a very large craniectomy—almost a hemicraniectomy, and as a consequence the unfolding of the dura from the eminences and depressions on the inner side of the cranial vault—only a very small additional amount of fluid found its way into the intradural cavity.

FERRIER belongs to that small group of illustrious men who re-created and re-discovered the science of experimental neurology, lost to mankind since the times of Galen. Ferrier was experimenting before Horsley, Beevor, or myself were students of medicine. His first experimental paper was published in 1873, and he wrote on pain in the head and vomiting in cerebral disease. Besides marking out with precision the motor areas of the cortex he discovered the areas concerned in special sensation. His experiments leading to the discovery of the visual centre and to the understanding of the symptom hemianopia mark an epoch in our knowledge.

BROCA in 1861 showed at a meeting in Paris the brain of a man who for twenty-one years had lost the faculty of speech. There was softening of the third left frontal convolution.

CRUVEILHIER in 1829 had under his care a woman, aged 45, in whom the symptoms noted were frontal headache, weakness of the left leg, slow speech, mental enfeeblement, and involuntary micturition. He diagnosed a tumour of the right frontal lobe, and a month later had the satisfaction of demonstrating to his class at the autopsy the tumour in the situation in which he had predicted that it would be found. Cruveilhier knew, as Hippocrates did, that a lesion of one side of the brain was not seldom associated with paralysis of the opposite side of the body. It is of interest to me to remember that my late friend Charles Beevor contributed a paper on involuntary micturition, an early symptom of frontal lobe disease.

HEYMAN in 1831 had under his care a girl of 13 years who had been struck on the left side of the head with a garden rake by a playfellow. The wound healed, and some months later convulsions occurred. It was noticed that tremor of the right hand occurred at the commencement of each attack. The scar over the left parietal bone was tender. The bone in this region was exposed, and a trephine $1\frac{1}{4}$ in. in diameter was applied. The dura beneath was discoloured. It was incised, and a yellow tumour of the meninges was removed. Complete recovery ensued. From my recollection of the eighties of last century I feel sure that if this operation had been done then by, say, Horsley or Macewen it would have been hailed as a miraculous achievement.

FRITSCH and HITZIG in 1870 marked out certain centres in the brain by means of electrical stimulation, but, as Macewen states, their force and significance were not recognized till Ferrier's observations on the brains of animals were published in 1873. These were undertaken to put to experimental proof the views entertained by Hughlings Jackson. I was present, newly qualified, in the Physiological Section of the International Congress in London in 1881. There was a contest of transcendent moment to the advancement of knowledge and vital to the interests of mankind over the dog shown by Goltz and the two monkeys exhibited by Ferrier. Experimental injuries had been inflicted upon the cerebral cortex of each of these animals. The dog apparently was in a normal state; Goltz spoke of the utter folly of the view that special parts of the brain are peculiarly associated with certain functional departments. This reminded me of a lecture I had attended the previous year in which we were told that the brain functioned as a whole! One of the monkeys had characteristic cerebral hemiplegia; as it came into the room Charcot exclaimed, "It is a patient." The other monkey showed no sign of hearing when a percussion cap was snapped in its immediate neighbourhood.

In 1883 Ferrier gave the Marshall Hall oration. He said that up to that time cerebral localization had been absorbed like latent heat by medical science itself, as distinct from medical and surgical practice, but that the unfailing safety of experiments upon animals made it clear that similar results would soon be achieved on man himself. This forecast soon became true: Godlee removed a brain tumour in 1884.

SCHAFER contributed twenty papers of transcendent merit between 1883 and 1893. They were all papers on cerebral physiology, and it is very difficult for us to apprehend the enthusiasm, the industry, and zeal of such labours. It is said there is a rhythm in human affairs, an alternation of efflorescence, decay, and efflorescence again, but in our country, in the fruitful lives of Ferrier, Hughlings Jackson, Schafer, Sherrington, Horsley, and Henry Head, there was no hint of decay but a continuing efflorescence, becoming brighter and brighter as the years rolled by. This, indeed, was the golden age of experimental neurology. We neurological surgeons owe an incalculable debt to these great leaders of science, since without the knowledge gained by

them there would be no neurological surgery as we understand it to-day.

Following on the demonstration by Ferrier of the truth of cerebral localization there ensued a tremendous activity designed to elucidate the physiology and anatomy of the nervous system. Even I had a small gamble in the same direction: stimulating the cortex and internal capsule of monkeys. In one experiment in which I was engaged, with my colleague, the late Dr. Hadden, in stimulating the extreme upper part of the Rolandic cortex in the monkey, movement of both big toes was observed. On stimulating the corresponding area of the opposite Rolandic cortex no movement of either big toe occurred. I have on several occasions stimulated the brain of man, but have never seen movement of both big toes from excitation of the upper part of the Rolandic cortex on one side of the brain. Between 1884 and 1891 Horsley produced eight papers of extraordinary value, and a little later, with Clarke, another one of great anatomical interest entitled "The intrinsic fibres of the cerebellum, its nuclei and efferent tracts." In 1886 and 1887 Horsley published cases of operation for brain tumour which were noteworthy because the diagnosis of each case was discussed with reference to his experimental work on the brain of the monkey.

In 1888 MACEWEN gave a splendid address in Glasgow on the basis of twenty-one operations for cerebral disease and injury. The first case occurred in 1879.

KEEN published three cases in 1888, one being a large meningeal tumour successfully removed from the fronto-parietal region.

SHERRINGTON'S contributions to neurology are so immense that it is quite hopeless to attempt any record, and to mention but a few would only be to leave others out, perhaps of still greater import. Suffice it to add that these papers of our emeritus honorary member number more than 150. But I should like for a moment to refer to two addresses given by Sherrington, (1) "The final common path of reflex action," and (2) "Aspects of animal mechanism." The wording of these addresses is typical of all Sherrington's writings. The choice of words, the grouping of words into sentences, and the perfection of the language of each paragraph are so clearly Sherringtonian that if these addresses had been published anonymously I could without any doubt have named the author. Take a single sentence as an example. How could words be better chosen and arranged? "Each insight into mechanism reveals more mechanism still to know."

There is one paper which, however, I must mention. It was entitled "The formation of scar tissue," and I was very fortunate in being associated in a minor way with Sherrington in the experiments on which the conclusions of this paper were based. The paper was published in the *Journal of Physiology* in 1889. The result of this research has given me, as it gave the late Professor Shattock, and that splendid surgeon Marcus Beck (as he himself told me), a vision of the cellular processes, not only in a healing wound, but also in disease, which has been of incalculable value to me all my professional life. The next year (1890) a lantern demonstration of the experimental results was given in Berlin in the Pathological Section of the International Medical Congress, and in the discussion which followed a dramatic incident occurred—Ziegler threw over his previous belief in Cohnheim's views and accepted the conclusions of Sherrington and myself with regard to the conduct and fate of the leucocyte and connective tissue cell.

I have seen it stated that Harvey was the first experimental physiologist, his great work *De Motu Cordis et Sanguinis* being published in 1618; but Galen was the first experimental neurologist. He produced aphonia by cutting the recurrent laryngeal nerve. He divided the spinal cord at different levels and removed portions of the brain, so obtaining definite results concerning the cause and seat of various paralyses. Celsus and Galen must have gained much from the learning garnered in the schools of anatomy in Alexandria in 285 B.C. under the famous teachers Erasistratus and Herophilus besides being the lineal and near descendants of the Hippocratic tradition. Celsus describes how blood effused beneath the skull causes pain and dimness of vision, and states that it should be removed by trephining. These great men must have had some idea of a blood current. They could not have been wholly ignorant of the physiology of the vascular system. How could Celsus have written *Sanguinis cursus revocetur* without having some idea of a blood current? Is it not more likely that, as Ambroise Paré in 1570 rediscovered the use of the ligature "by the special favour of the Sacred Deity," so Harvey in 1618 redemonstrated to the modern world what had been understood, perhaps only dimly, by Celsus and Galen?

It has been said that JOHN HUNTER, as physiologist and surgeon, has no equal in the annals of medicine. Even our emeritus honorary member Sir Arthur Keith could hardly improve on the description of John Hunter written by Sir William Laurence: "It was the boast of Augustus that he found Rome built of brick and left it built of marble. Hunter found surgery a mere mechanic art. . . . He left it a beautiful science."

Besides Sir David Ferrier, Sir Edward Sharpey-Schafer, and Sir Charles Sherrington, we welcome to-night Sir Arthur Keith and Professor Elliot Smith. We are very proud that they all have consented to join our young society. We greatly admire the labours of Sir Arthur Keith and Professor Elliot Smith in anatomy, physiology, morphology, and anthropology. We recognize the need for the study of function as an essential part of the interpretation of anatomical structure. As an example of this truth Professor Elliot Smith writes:

> "The knowledge of the arrangements of the tracts in the spinal cord that has been acquired within recent years seemed at first to have been of little more than academic interest or at most of use in diagnosing lesions beyond the scope of treatment till Spiller in 1911 suggested that the knowledge could be put to the humanitarian purpose of relieving pain by cutting that part of the antero-lateral column of the spinal cord which conveys impulses provocative of pain."

In the words of the professor in his recent Thomas Vicary Lecture, we believe that the apprehension of the true significance of anatomy and its study on the right lines will raise the standard of the science and practice of surgery.

Larrey and Guthrie were the great surgeons of the Napoleonic wars. LARREY was at first a naval surgeon, and in order to reach his ship he walked from Paris to Brest. Larrey observed some important effects of injury to various regions of the brain and noted facts of importance in cerebral localization—for example, contralateral palsy, loss of memory, aphasia; also that when paresis is caused by a cerebellar lesion it is on the homolateral side. He relates one case of Jacksonian epilepsy which he cured by operation. He states that his cases did better when left out on the road than when shut up in churches or hospitals, whether in the heat of Egypt or during the rigours of a Polish winter.

GUTHRIE, like Larrey, was a great army surgeon before the Listerian era. Both had extensive experience of war injuries of the head. Guthrie is the historian of the surgery of the Peninsular war, and records a large number of cases. He says all depressed fractures must be operated on and that the dura must be incised to let out blood or pus.

Guthrie was a strong opponent of the mediaeval practice of repeated trephining which had survived to his time, and he quotes the following case in support of his views:

> "Philip of Nassau, having been thrown from his horse, fractured his skull by striking his head against the stump of a tree. He was trephined twenty-seven times by a surgeon of Neomagen. He gave a certificate of this signed by himself; and as a proof of his complete recovery drank three of his companions to death."

But I must end. We live in an age when the great discoveries of Morton and Simpson, of Pasteur and of Lister, and of the great experimental neurologists have been applied to surgical practice. Lister is the upper light of surgery, but there is no last finish in the path of surgical progress. We are pilgrims of surgery who have reached only the threshold of truth. It is for this young society to carry on the torch and keep it brightly burning.

SPEECHES BY EMERITUS HONORARY MEMBERS.

SIR DAVID FERRIER.

I consider it a great honour and privilege to be invited to this the inaugural meeting of the Society of British Neurological Surgeons. This is the age of specialization in medicine, and specialization is essential to progress. Narrow specialism is to be deprecated, but this cannot be said of the special surgery of the nervous system. Neurology is perhaps the most comprehensive specialty in medicine, and the neurological surgeon must be, not only a highly expert technician, but also, unless he is content to be a mere tool, well versed in neurology and neuropathology.

I have followed the evolution of cerebral surgery for the past fifty years. My own experiments on animals, and the application of the antiseptic methods of Listerism, led me to advocate operations on the brain as being likely to achieve as brilliant results as those of abdominal surgery. This, however, was at first viewed askance, and the *Lancet* (November 10th, 1883) remarked that very few would be likely to share my anticipations, as "the differences between the abdomen and the skull are more than even antiseptic surgery can annihilate." How changed have become views as to the sacredness of the intracranial cavity!

The first operations on the brain were relatively simple, and met with only moderate success. I was present at the first operation for removal of a cerebral tumour by Mr. Godlee in 1884. This case was at first successful and full of promise, but unfortunately the patient died from septic complications. I was present also at Horsley's first operation in 1886—the removal of a traumatic epileptogenic focus in a patient under my own care. This was a triumphant success. But many failures continued to be reported. Within the last few years, however, cerebral surgery has made enormous strides; improvements in technique and the more precise knowledge that has been gained as to when to attempt removal of a tumour and when to be content with decompression as a palliative have made cerebral surgery a relatively safe proceeding. Some tumours—the acoustic tumours—the removal of which was at one time uniformly fatal, can now, thanks to Cushing, be removed with absolute safety. Pituitary tumours, involving the most profound invasion of the intracranial cavity, can to-day be satisfactorily dealt with; and the avulsion of the fifth nerve root for inveterate trigeminal neuralgia is an almost daily and successful method of treatment.

Spinal surgery has also many triumphs to boast of. The exact localization and removal of spinal tumours, since the first case recorded by Gowers and Horsley forty years ago, have been uniformly successful; and the more recent operations for division of the sensory tracts of the spinal cord for the relief of incurable suffering are a promising and fruitful application of neurological science to practical medicine.

The surgery of the peripheral nervous system, at present so diligently cultivated by our distinguished chairman, requiring as it does great manipulative skill and exact anatomical knowledge, is another field of neuro-surgery which is likely to furnish us with valuable information as to the best methods of obviating the disabilities and deformities resulting from permanent nerve lesions. Considering the progress which has already been achieved in so many directions, I am confident that the intensive cultivation of neuro-surgery will not only provide relief for many forms of disease at present beyond our aid, but materially advance the science of neurology itself. I therefore cordially wish all success and prosperity to the newly formed Society of British Neurological Surgeons.

SIR EDWARD SHARPEY-SCHAFER.

I beg to thank the members of the Society for the honour they have done me by electing me an Honorary Member—an honour I appreciate the more on account of the fact that I am sharing it with eminent anatomists as well as other physiologists; and especially to thank your President for the generous terms in which he has referred to my small efforts. It is just fifty years since I was taking a very subordinate part in the birth of the Physiological Society, the founders and original members of which are all dead, with the exception of two—Sir David Ferrier and myself—who have the good fortune, not only to be still alive, but to be both present at this inaugural dinner of your Society. The Physiological Society started by limiting the number of its members to forty. In a year or two so great was the demand for admission that the number was raised to 50; now it runs to 400! That society was also started by a dinner, the menu of which is preserved in the old minute-book and does credit to the gastronomic ability of the original members. Michael Foster was in the chair, and was supported by Francis Galton, George Henry Lewes, J. Burdon-Sanderson, and about eighteen younger members who were interested in or working at physiology. On that occasion there were only three toasts: The Queen, naturally first; then the Foreign Guests, responded to by Professor Donders and Professor Marey; and lastly, the English Guests, responded to by Dr. W. B. Carpenter and Mr. William Bowman.

Singular to relate, the health of the new-born society was not drunk, and, still more singular, it has grown and flourished amazingly in spite of the omission. Nevertheless, I am of opinion that such an omission should not be taken as a precedent, and, with the permission of the President, I beg to raise my glass to the health and prosperity of your new-born babe, the Society of British Neurological Surgeons; long may it flourish!

SIR ARTHUR KEITH.

I give you my most sincere thanks for the privilege of being present at the birth of this Society. That your Society has a long future and will fulfil a high destiny I have no doubt. I have noticed that the medical side of neurology has always attracted the most gifted of physicians, and I am sure the surgical side of this subject will draw to it the corresponding class among surgeons. Young men are attracted by subjects which give scope for the exercise of reason and of all branches of medicine. Neurology gives the fullest opportunity; it has a better claim than any medical subject to be counted a science.

Sir David Ferrier has mentioned the case in which Dr. Hughes Bennett and he diagnosed and localized a lesion of the cortex, on which Sir Rickman J. Godlee operated on November 25th, 1884—the first operation for the removal of a tumour which had been localized by the interpretation of clinical signs. The calvaria of the patient, showing the situation and extent of the operation, was presented to the museum of the Royal College of Surgeons of England by Sir Rickman Godlee, and there it is now exhibited amongst specimens of historical interest. Beside it are shown instances of prehistoric trephining.

I have greatly enjoyed being seated next to Sir David Ferrier. There is something of a coincidence in my being his neighbour to-night, for some sixty-five years ago his people and my people were neighbours and saw much of each other. By the time I reached boyhood Sir David had gone to London and had become famous, and I cannot remember seeing him then. But my mother always spoke of him in the highest terms; in her opinion he had only one blemish as a young man: he would not leave the "puddocks" (frogs) alone! We thus see that Sir David had discovered at a very early date that experiment is the doorway to knowledge.

PROFESSOR ELLIOT SMITH.

After expressing his appreciation of the distinction of being associated as an honorary member with such great pioneers in neurology as Sir David Ferrier, Sir Edward Sharpey-Schafer, and Sir Charles Sherrington, Professor Elliot Smith referred to the urgent need for closer co-operation in neurology between the anatomist and the clinician, which was essential for the advancement of knowledge in both departments of work. He expressed the opinion that the first step towards the attainment of such an association must be taken by the anatomist, who should cultivate such a knowledge of the structure of the nervous system as would make it worth while for the clinician to consult and collaborate with him. The problems that arose in the course of clinical work provided the most suggestive and stimulating incentives for morphological investigation.

British Medical Journal.

SATURDAY, JANUARY 8TH, 1927.

MATERNAL MORTALITY.

THE problem of the persistence of the mortality rate in connexion with pregnancy and childbirth in this country has excited considerable discussion of late years, and references to the subject have appeared in our columns with increasing frequency. Dame Janet Campbell's report to the Ministry of Health and the report of the Scottish Board of Health's Departmental Committee have served to focus the attention of the profession upon the main difficulties of the question. As is well known, the British Medical Association has a committee in existence at present to consider the same question; its preliminary report was published in the SUPPLEMENT to the JOURNAL of January 9th, 1926 (p. 13), and its final report will be awaited with interest. In the meantime any really reliable evidence bearing upon this problem is of great value. Individual experience is apt to be fallacious in a question of this nature, although the accumulated personal observations of a large number of practitioners must ultimately form the groundwork for any conclusions. Dr. J. S. Fairbairn has gone to considerable trouble to contribute a valuable piece of evidence in the presentation of the maternal mortality statistics in connexion with the midwifery service of the Queen Victoria's Jubilee Institute. As will be seen from his article published in the opening pages of this issue, the figures he is able to deal with are large enough to warrant him in basing some interesting conclusions upon them.

Two main lines of opinion have emerged from the discussion so far. On the one hand there are those who see salvation only in a great extension of specialist practice; who would have maternity hospitals established widely over the country and staffed with skilled specialists; and who would have something in the nature of an outdoor hospital service radiating from each centre in such a way as to meet the needs of the whole country. Those who share this opinion tend to regard the practice of the midwife with some disfavour, and would transfer the maternity work of the country from her hands to those, not merely of the medical practitioner, but as far as possible of the obstetric specialist. Whether we agree with this opinion or not, it certainly does not seem a practicable proposal in these days of burdensome taxation, as the cost alone would be prohibitive. On the other hand, there are those who put their trust rather in the improvement of the existing services of midwife, general practitioner, and hospital specialist. As was pointed out by the Scottish Departmental Committee, there is no real competition, and there should be no feeling of rivalry, between the medical practitioner and the midwife. The two are complementary members of the maternity service of the country, and should work in harmony with each other and with the hospital and specialist services. Except in the case of the few protagonists of one view or another, opinion on this question has not become crystallized, and while it is still in a fluid condition such evidence as Dr. Fairbairn has produced is of great value.

It has been claimed ere now that the mortality rate in the practice of competent midwives is on the whole distinctly lower than the general maternal mortality rate revealed by the Registrar-General's returns. Evidence on this point was laid before the Scottish Departmental Committee, and it was also shown that in the practice of some individuals where, after adequate ante-natal examination of all cases, the normal ones were left to the midwife and the abnormal ones supervised by the practitioner or sent in good time to a maternity hospital as the case might be, the frequency of instrumental intervention was definitely diminished and the results improved *pari passu*. This might almost be said to be one of the general principles which derive from the practice of ante-natal examination, and to those who are familiar with the value of such work the results claimed are just what would be expected. In the Queen Victoria's Jubilee Institute the country has an organization of fully trained nurses who have also taken their complete maternity training. Such a combination of general nursing and maternity training is, of course, the ideal, as even the increased period of training now demanded by the Central Midwives Boards can never be expected to equal, in the breadth and value of the experience gained, the three or four years' training in a general hospital. In the practice of the Q.V.J.I. nurses, therefore, we might, on the basis of this evidence, reasonably expect the results to be rather better than the general returns of the whole country, and this is exactly what Dr. Fairbairn has demonstrated.

The circumstances of their practice necessitated some modification of the statistics so as to make them strictly comparable with the figures of the Registrar-General. This part of the preparation of the figures was undertaken by Dr. Matthew Young of the statistical department of the Medical Research Council, and it seems to us to be adequate to allow of fair comparison. The result, as illustrated in the chart, indicates that the maternal mortality in the practice of the Q.V.J.I. nurses has during the past twenty years been rather less than half the general maternal mortality rate in England and Wales as shown by the Registrar-General's returns. This is a result which is not merely highly creditable to the nurses concerned, but which must give all who are interested in this great national problem cause for reflection. Beyond that we are not prepared to go at the moment, because, as we have said, the whole problem is at present *sub judice*; but there is no doubt as to which view of the solution of the maternal mortality problem this evidence supports.

Dr. Fairbairn's investigation brings out many other interesting points with which he deals in some detail. Thus the number of cases attended by the Q.V.J.I. midwives was 4,500 in 1905 and 47,926 in 1925. These figures also speak for themselves. Again, the proportion of cases in which medical aid was summoned was 8.9 per cent. in 1905 and 26 per cent. in 1925. This increase is partly attributable to the general tightening up of regulations by the Central Midwives Boards, but Dr. Fairbairn regards it as in some degree due also to a diminished self-reliance on the part of the nurses. There can be no doubt that one of the desiderata in this whole problem is to impress, not only upon nurses and practitioners, but also upon patients, and above all upon patients' immediate relatives and friends, the value of non-intervention in natural and uncomplicated labour. It is a difficult thing for the young practitioner or for the nurse to resist the pressure which relatives often exercise in favour of instrumental intervention, which puts a speedy termination to the patient's physical sufferings.

Dr. Fairbairn recommends the judicious administration of narcotic drugs, and with that recommendation no obstetrician will differ, but the broad fact remains that in these days of easy and safe anaesthetics we are coming as a people to have what our grandmothers would call an undue dread of physical pain.

HEREDITY IN MUSIC.

To reckon musical talent among the familial diseases would perhaps be going just a shade too far, and yet Dr. Louis Vezoux, in his Paris thesis,[1] musters nearly enough facts to justify such a view. His survey is careful and interesting, even though it contains few new facts. Nordau had observed how frequently an exceptional development of musical talent is associated with an otherwise subnormal mentality. Dr. Vezoux seems carried away by a similar prepossession, although he does not claim it as an essential part of his thesis. He sets out to show how musical talent is one of the most notable gifts of inheritance, how it appears to be almost ineradicable from musical families, and how impossible it is to implant it in members of non-musical families. But into the explanation of these phenomena he does not pursue his quest. The possessors of musical talent are divisible into three main groups: first the composer, next the performer, and finally the hearer. In any discussion of musical talent these three often require separate consideration; few people possess the ability of each category in equal degrees. The study of the question takes us back to all manner of problems in comparative physiology and psychology, and without some knowledge of these problems the study will prove barren and futile. The power of artistic thought and the power of expressing it in works of art are attributes of man alone. No animal can reproduce its observations and ideas in pictorial form—even artifice in personal adornment is only exhibited by the bower bird—whereas the faculty of making both vocal and instrumental music is one that man shares with beasts, birds, and insects. Yet just as among closely allied birds one breed may be abundantly musical whilst another is wellnigh mute, so among men the musical breeds are few and talents unequally distributed, until the inquirer begins to doubt whether music is, in the strict sense, art at all, or even an acquired characteristic. If we remember rightly, Bernard Shaw, in one of his letters to Miss Viola Tree, says: "Don't you know that no one was ever taught to sing, unless perhaps by her mother?" He was, unknowingly it may be, insisting on the hereditary nature of the gift of song.

It is interesting to speculate how the musical variety of the genus Homo came to survive even in such small numbers as it does. It first appeared, we may guess, as a "sport," and as such contributed in some way to the superiority of the individual or the race in the struggle for existence. What improvement in equipment for the struggle can the gift of music have represented? It is hard to conceive any but two primitive values for music. Mountain dwellers must have discovered very early that by means of certain cadences or intervals in the voice a shout could be made audible and intelligible over great distances. Nursing mothers found, to the delight of themselves and their husbands (weary and irritable after a day's hunting), that rhythmic song and measured cadence, no less than rhythmic rocking, could lull a baby to sleep and secure rest for the whole cavernful. The employment of music to arouse the passions of love and anger must be a much later development. But there is evidence on all sides that it did so develop, and closely allied to this evolution of music is its relation to mental stability.

Dr. Vezoux seems to suggest that we owe to some mental unbalance many of the world's greatest composers and performers; the hearer may occasionally escape with his sanity. For instance and parallel he turns to the maniacs, who sing melodiously in their frenzy, and to the effect of drugs like hashish. Precocity, he observes, is almost the rule among musicians: the greatest composers and performers were almost without exception prodigious in infancy. No one can doubt that their precocity was inborn, that they inherited everything, owing little or nothing to musical education and environment, though they may suffer by a lack of general education, which Cortot is quoted as deploring among young people who devote themselves to music. It is incredible that composers who, like Mozart and Schubert, wrote mature works while still mere children, depended on any acquired art for the development of their faculties. They learnt, it is true, how to express in conventional signs sounds which originated spontaneously and uncontrollably in their brains, and acquired the art of setting accepted symbols on the ruled lines of a musical stave. No "theory of music" taught their brains to work; such theories only serve to help the hearer to explain why he likes or dislikes the music the composer invents or the performer interprets. Dr. Vezoux's thesis throws a vivid light on the nature of those men in whom the power exists of creating coherent sequences and combinations of sounds that please the ear, but he does not advance our understanding of the whys and wherefores much beyond the stage of Burton's remark that "*music makes some men as mad as tygres.*"

PRESERVATIVES IN FOOD: THE NEW REGULATIONS.

PURER food, and consequently improved health, should result from the Public Health (Preservatives, etc., in Food) Amendment Regulations, 1926, which came partly into operation on January 1st All foods are concerned except three classes, of which the first includes bacon, ham, egg yolk, and articles containing preservative necessarily introduced by the use in their preparation of preserved margarine. The regulations for this class do not become operative until July 1st, and, after a further six months, butter, cream, and articles of food containing preservative necessarily introduced by the use in their preparation of preserved bacon, ham, egg yolk, or cream, will similarly be affected. On July 1st, 1928, the regulation will be extended to cover food in the preparation of which preserved butter has been previously used. These regulations owe their origin in considerable measure to the Departmental Committee on Food Preservatives, and in discussing its report (BRITISH MEDICAL JOURNAL, 1924, vol. ii, p. 821) the opinion was expressed that such changes as those now made could be effected without increasing the cost of food, and that the prohibition of the use in food of so insidious a substance as boric acid would be to the public benefit. The general nature and scope of the regulations were indicated in our issue of August 22nd, 1925 (p. 349), and attention was then drawn to some of the legal questions concerned. In the last circular of the Ministry of Health (751) the view is expressed that sufficient time has now elapsed for clearing the old stocks of food, and that further postponement of the regulations is unnecessary. The suggestion is made, however, that local authorities might refrain

at first from instituting legal proceedings for infringement of the regulations in cases where they are satisfied that reasonable efforts have been made to clear the old stocks and to ensure that further consignments will conform with the new conditions. By a modification of the original regulations it has been provided that their enforcement in respect of imports of fresh fruit (excluding pulp), in common with meat, fish, and their products, will normally be left to local authorities. The principal regulations, with such modifications, are being reprinted, and will be obtainable through any bookseller or from the Stationery Office. It is intended that cold storage shall replace in great measure the adding of preservatives to food. The regulations contain a schedule of articles of food which may contain such preservatives as sulphur dioxide and benzoic acid, the allowable strength being specified in each case in parts per million. Foods which may be preserved in this way include sausages, fresh or dried fruit, unfermented grape juice, non-alcoholic wines, cordials, fruit juices, jam, candied peel, sugar, gelatin, beer, cider, alcoholic wines, sweetened mineral waters, coffee extract, and pickles. Metallic colouring matters containing compounds of antimony, arsenic, cadmium, chromium, copper, lead, mercury, and zinc are prohibited; also the vegetable dye gamboge, and some coal-tar colours, including picric acid. Foods containing permitted preservatives are to be labelled accordingly, the percentage of the preservative being stated. It is noteworthy that under the new regulations the manufacture, as well as the sale, of foods containing unauthorized preservatives or colouring matter is forbidden. This may be expected to assist local authorities in fulfilling their duty of securing compliance with the regulations. Preservatives which may still be used include common salt, saltpetre, sugar, acetic acid, alcohol, glycerin, spices, essential oils, and herb extracts.

LEGIBILITY OF PRINT.

AN interesting research into the "legibility of print"[1] has been carried out, under the auspices of the Medical Research Council, by Mr. R. L. Pyke, in the Psychological Laboratory of the University of Cambridge. The intention has been to determine what characters of type are most easily read. Reading by way of work or recreation takes up much of the active life of a large proportion of certain classes of the population, so that legibility of type is nowadays of high importance. Many previous investigations have been made or opinions published (an extensive bibliography is given), and besides there has grown up a practice based upon trial and error. It is of interest to note that the general conclusion of the experiments of Mr. Pyke confirm the common impression that a certain kind of type is the most generally comfortable, and it is this which is most in use, certainly in this country. This type goes by the name of "old style." Legibility has to do with reading. Normal reading refers to an act performed most commonly by an individual in an ordinary sitting position in a full light, with words set in horizontal lines one below the other, printed, as to about 90 per cent., in lower case (that is, small letters), as to about 10 per cent. in upper case (that is, capitals), in black ink on white or cream paper. The matter is held at distances from the eye varying from six to sixteen inches. Legibility of type means that the eye is able clearly to define the shape of a letter, the collective shape of a word, and, in continuous texts, can read accurately and fast. About the best available criterion is the number of errors committed in any test with a time element. An elaborate piece of apparatus was devised to expose print for brief and repeated spaces of times, under a uniform illumination, to each of a set of readers the state of whose vision was known; the results of the exposure of different kinds of print were ascertained, and most careful precautions were taken to eliminate error. No subject tested had any knowledge of psychology; each was informed of the object of the experiments, but was given the least information possible of the results of his own performance or that of others under test. The qualities in type that were considered fundamental were lateral extension of face, lateral compression of face, uniform thickness of limb, uniform thinness of limb, and absence of serifs (that is, the tags to the letters). The results of the tests show that the standard "old style." is best, being 18 per cent. better than the next, and 70 per cent. better than the worst. The second best was a "sans serif" type—that is, plain, undecorated letters, such as used in many advertisements. The difference was only 2 per cent. between the thick and the thin types. No difference was found between the compressed and the extended. To sum up the laboratory experiments, "old style" was probably the most legible, and the compressed "modern" the least. But it is suggested that types will be "legible" according as they suit the psychological make-up of the reader. Hence the most legible type, in the subjective sense, is unlikely to be the same for all readers. Perhaps this may account for the fact that whereas we in England prefer and most of us choose "old style," the French largely use a tall type which gives what Harman once called a "palisade" effect, and the Americans a thin type, which goes with the fine smooth-faced paper they are so fond of. That there is a revived interest in good printing is evidenced by the exhibition of newly printed books which has been displayed by the Bibliographical Society in the Mocatta Library at University College, Gower Street, London. The books shown are publications in the last two years. They were selected, not by the society, but by the publishers themselves, who were each invited to send five books illustrating their methods and the ideas by which they are guided. Some thirty-three publishers took a share in the exhibition, and the works of forty-nine firms of printers are on view. The collection is most interesting, and is real evidence of care and judgement. There is a happy absence of freak types of the kind which had a short-lived popularity some twenty years ago. Those interested in books might spend a profitable hour at the exhibition.

TOP MINNOWS AND MOSQUITO CONTROL.

THE use of various species of Gambusia, a natural enemy of larvae and pupae of mosquitos, as one of the many modes of eliminating Culicidae, has been known for a long time, but a recent Bulletin of the United States Public Health Service[1] has taken the subject out of the category of mere empiricism to place it upon a rational basis. This bulletin is full of interesting facts, the data for which were almost entirely derived from experimental work. Experiments and controls were numerous, and we can unfortunately do little more here than indicate the methods, purposes, and range of them. Sections of ponds in various situations were rendered fishless, others under as nearly as possible the same surroundings were employed for control, so that the differences in the mosquito breeding would result in the main from the presence or absence of fish. By carrying out the experiments for three or four seasons, and using ponds with different forms of vegetation, much knowledge has been gained as to the value of Gambusia as eradicators of mosquito larvae and pupae under a wide range of conditions. These fish had been found to vary in

[1] *A Study of the Top Minnow (Gambusia holbrooki) in its Relation to Mosquito Control.* Public Health Bulletin No. 155. Treasury Department, United States Public Health Service, Washington, D.C.

efficacy in different districts, being less efficient in the northern parts of their range. This is probably due, not to the district, as was believed, but to the species of Gambusia; thus, *G. holbrooki* of Eastern Georgia differs in efficiency from the *G. affinis* of the Mississippi Delta region. After arranging the experimental and control conditions, as regards fish, vegetation, water-level, and so on, dippings (each "dipping"=twenty-four dips with a net) were taken, and the relative abundance of mosquitos breeding in the areas was calculated by counting the larvae and pupae recovered in each dip, anophelines and culicines being counted separately. Hundreds of experiments were performed, the results of which are narrated in the text and presented partly in tables, partly by means of graphs. The following are a few of the more important results and deductions. Silver-leaf grass (*Hydrochloa carolinensis*), pond-weed (*Potamogeton diversifolius*), milfoil (*Myriophyllum* sp.), bladderworts (*Utricularia* sp.), smartweed (*Polygonum* sp.), and several others tested each afford protection to the larvae from the attacks of the fish, but not under all conditions. Thus, milfoil protects if it grows sufficiently tall to reach the water surface, not otherwise. Again, if on clearing an area some sprigs of silver-leaf grass were left here and there, a scattered growth soon formed which afforded effective refuge to the immature mosquito, and thinning of the grass tended, paradoxically, to increase the available protection. The practical conclusion from this is that, from the point of view of mosquito control by fish, it is better not to disturb the natural growth of grass unless the latter is completely removed. Bladderwort had been reported by many observers as being antagonistic to mosquito production, but experiment failed to confirm this, and, moreover, if intermixed with filamentous algae it appeared to conduce to the better breeding of mosquitos by furnishing an excellent barrier between the fish and the larvae and pupae. Another interesting point as regards smartweed was investigated. It was found that when this was present, even in the absence of fish, the larvae were scarce. No complete explanation could be found for this; the plant did not act as a repellent, for if the water-level fell sufficiently to leave the plant exposed, larvae and pupae became abundant. The only plant which proved definitely preventive to mosquito breeding was duckweed (*Spirodela polyrrhiza*), and this was shown to be due, not to any specific action, but to the exuberance of its growth. If the weed was so profuse as to cover the surface breeding did not occur, but was resumed on clearing, to fall again when the weed was re-introduced; to prevent breeding the covering must be continuous. Its use, however, is very limited, because it will not grow in all waters, and in some of those in which it does it will not form a continuous coat. Generally it was found that "overstocking" with Gambusia, though leading to a little further reduction of larvae and pupae, had not a very pronounced effect, but beneficial results were sometimes obtained by artificially increasing the number of minnows in a body of water where they had been present for a long time, because a "biological balance" is liable to become established and further reduction cease. After heavy rains a diminution in the breeding of mosquitos was noticed in the ponds whether Gambusia was present or not. In the former case the minnows always seemed to be more active after rains, and the explanation given is that the increase of water caused submerging of the vegetation and consequent reduction of protection of the larvae. This, however, would not account for reduction in fishless areas. It was found generally that maximum protection was afforded by plants with partly or just submerged leaves, so that only a thin film of water was present in which the mosquitos might breed. *Gambusia holbrooki*, which was the species used in these experiments, proved more efficient in eradicating culicines than anophelines. Attempts were made to find out—obviously a very difficult problem—the proportionate number, in a pond well stocked with Gambusia, of immature mosquitos present which reached the imago stage. As far as careful experiments could decide, it was found that only 2.75 per cent. of anophelines and 1.5 per cent. of culicines survived. It is important to note that absence or scanty breeding of mosquitos is not always the result of the presence of natural enemies; in some ponds, apparently ideal, they would not breed, although the conditions seemed to be in all respects—vegetation, situation, exposure, etc.—identical with others in which there were abundant larvae. The subject is a large and important one, and this bulletin, full of interesting information, has done much to elucidate many problems hitherto obscure.

AN ULTRA-VIRUS OF TUBERCULOSIS.

WE gather that at the meeting of the Académie de Médecine on December 7th, 1926, some heat was generated during the discussion of Dr. Couvelaire's paper on the ultra-virus of tuberculosis, noted in our issue of December 18th, 1926 (p. 1189). After Dr. Emile Sergent had described some not very convincing experiments made by Dr. Durand, Dr. Benda, and himself on material obtained from thirteen tuberculous women and two guinea-pigs, Dr. Léon Bernard reaffirmed the position of sceptic which he had taken up some months ago. Dr. Bernard did not dispute the existence of a filterable virus of tuberculosis which could pass through the placenta. But he saw no reason to suppose that the bacilli found in the viscera of some infants had anything to do with their death. On the other hand, he was impressed by the statistics of Dr. Couvelaire, which showed that the better the conditions of nurture of the infants in his clinic the fewer the deaths. It was more logical, he argued, to attribute the deaths to the environmental conditions than to inheritance of tuberculosis. The balance of opinion would, he suspected, be upset if the belief that tuberculosis could be inherited were revived, and the public thus encouraged to attach less importance to shielding infants from contagion. Drs. Sergent, Arloing, and Couvelaire indignantly repudiated any intention of minimizing the importance of post-natal antituberculosis prophylaxis; at the same time they urged that researches into the problem of the transmission of tuberculosis *in utero* should not be throttled by such considerations as Dr. Bernard had advanced. Why the transmission of a filterable virus through the placenta should be more an inheritance than the transmission of a non-filterable virus through the mother's kiss is, perhaps, a problem worthy of consideration.

FIRST AID IN ROAD TRAFFIC.

DEALING with the question of road accidents, the latest report of the Home Service Ambulance Committee of the Order of St. John and the British Red Cross Society expresses the opinion that with the increase of road traffic that will come with the revival of trade, there must be, for some time to come, a great number of road casualties. Ambulances alone will not suffice to meet the needs that arise from accidents on the highways; indeed, many of the injuries, while they call for skilled attention to prevent more serious developments, do not need an ambulance at all. Provided that an adequate supply of bandages and dressings is on the spot, and that skilled hands are available to apply them, most of the cases can be sent on their way. The Order and the Society therefore propose to give every encouragement to members to undertake in their spare time to help on the roads where the traffic is thickest and give first aid to injured on the spot. It is

intended that all the main highways of the country shall be equipped at suitable points with first-aid boxes containing all that is necessary for first aid to the injured, and that at busy periods, especially at the week-ends, voluntary trained workers shall go out prepared to exercise their skill in minimizing the effects of traffic accidents. With the toll of the road now approaching 150,000 a year in killed and injured—or over three times the total British killed, wounded, missing, and prisoners in the South African war, and not far short of four times the number of wounded in the second battle of Ypres—there is ample scope for voluntary effort to minimize the disastrous effects that modern traffic conditions have created. A national first-aid road service carried out in friendly co-operation with the police and the motoring organizations will be an undertaking worthy of the traditions of the Order and the Society. The committee has now 383 motor ambulance stations, and the number of patients carried is over 80,000 a year. Inquiries and offers of service may be addressed to the Secretary at 19, Berkeley Street, London, W.1.

UNATTENDED MOTOR CARS.

IN the *Times* of December 30th, 1926, there was a letter, of some interest to medical practitioners who drive their own motor cars, from a correspondent who had witnessed rather unequal distribution of justice in a London police court. Some eight or nine defendants had been summoned for obstructing traffic by leaving their cars unattended in a side street. We are not concerned with the correspondent's difficulty in understanding the magistrate's reason for imposing on a woman, who boldly pleaded that she had gone shopping, nearly twice the fine he inflicted on men who alleged urgent business. But we agree with the editorial comment that this matter of alleged obstruction by unattended cars "calls for properly co-ordinated and consistent regulation." A very large number of medical practitioners now drive their own cars when visiting their patients, and provided they adopt reasonable care in avoiding obstruction to traffic while in a patient's house, and do not occupy the roadway for an unconscionable time, there should be little reason for interfering with this custom. At all events, it is absurd that in some towns motor cars may be left unattended in front of shops, while in other towns, whose traffic problems are in all respects comparable, even the side streets are forbidden them. The motorist's difficulties are increased by the fact that no indication is usually given that standing of cars is not allowed. Though we have no desire to seek special privileges for doctors, we hope that due consideration of their position will be given in framing any general regulations that may be thought necessary.

THE ORIGINAL DESCRIBER OF PARALYSIS AGITANS.

THE series of interesting articles by Sir D'Arcy Power in the *British Journal of Surgery* on eponyms or authorities, such as Percival Pott and Sir James Paget, whose names are dutifully kept in remembrance for their additions to the corpus of professional knowledge, deserves the form of flattery said to be the most sincere. Perhaps this had struck Dr. R. T. Williamson,[1] who, after writing valuable monographs on various nervous diseases and on diabetes, turned his attention to medical history, and has recently published an account of James Parkinson and his "Essay on the Shaking Palsy" (paralysis agitans). He shows that "Parkinson's disease" is, at least from the patient's point of view, a preferable title, for those in an early stage may, as a result of accidentally hearing the name "paralysis agitans," live and be haunted for years with the constant fear of complete paralysis or helplessness. In our columns in 1923 (vol. ii, p. 25) was published a note by Professor Arthur J. Hall of Sheffield, in which he gave an account of Parkinson's life, and analysed his essay on shaking palsy which had then recently been reprinted by the *Archives of Neurology and Psychiatry*. He pointed out that Parkinson did not describe the facial expression, and that it was Sir William Osler, apparently, who gave currency to the term "Parkinson's mask." The credit of first describing the clinical features of paralysis agitans is, however, undoubtedly his; in 1817 his "Essay on the Shaking Palsy," in sixty-six pages, based on six cases, two of which were casually met with in the street, and another "only seen at a distance," was published. He must therefore have been a very acute observer, for his description is extremely good and he made suggestions about the pathology, stating that he published the clinical features of a condition previously unrecognized, in the hope that those who had the opportunity for pathological work might elucidate its morbid basis, and closes his essay with the rather remarkable words: "Every person of consideration and feeling may judge of the advantages yielded by the philanthropic exertions of a Howard; but how few can estimate the benefit bestowed on mankind by the labours of a Morgagni, Hunter, or Baillie." Parkinsonism as a result of epidemic encephalitis is a familiar term, but few there be who know that they are using the name of James Parkinson, surgeon and palaeontologist, who died on December 21st, 1824; Dr. Williamson has therefore done well to recall the details of this humble-minded pioneer's life in Hoxton Square.

[1] Williamson, R. T.: *Janus*, Leyden, 1925, xxix, 193-197.

NEW YEAR HONOURS.

THE announcement that the King, on the occasion of the New Year, had signified his intention of conferring a knighthood on Dr. Henry Head, F.R.S., will have been welcomed by all members of the medical profession as a recognition of Dr. Head's great services to neurological medicine and his brilliant contributions to knowledge of the nervous system. This honour comes appropriately soon after the publication in complete form of the record of his profoundly interesting and important work on aphasia and kindred disorders of speech, to which we devoted a leading article in our issue of October 9th, 1926 (p. 647). A knighthood is to be conferred also on Dr. Thomas Houston, director of the laboratories in the Royal Victoria Hospital, Belfast, and the pleasure that this announcement has given to the whole medical profession of Northern Ireland is recorded in another column by our Belfast correspondent. The C.B. (Military) is conferred upon Colonel Corrie Hudson, C.I.E., D.S.O., Assistant Director of Medical Services, Aden Brigade; and another officer of the Indian Medical Service, Lieut.-Colonel J. W. Cornwall, lately director, Southern India Pasteur Institute, Coonoor, is appointed C.I.E. This short list of medical New Year honours is supplemented by the announcement of two special promotions in the medical branches of the services: Surgeon Commander Leslie H. Morris, R.N., becomes Surgeon Captain, and Squadron Leader H. B. Porteous, R.A.F., becomes Wing Commander.

THE Medico-Legal Society has accepted an invitation from the Obstetrical Section of the Royal Society of Medicine to take part in a joint meeting on Friday, January 21st, at 1, Wimpole Street, W., at 8 p.m. The subject for discussion is "The ethical, legal, and medical aspects of abortion," and the speakers will be Dr. J. S. Fairbairn, Lord Riddell, Dr. T. W. Eden, and Sir Travers Humphreys. The Obstetrical Section has invited the President of the Medico-Legal Society, Lord Justice Atkin, to take the chair and to sum up the debate.

Ireland.

SIR THOMAS HOUSTON.

A CHORUS of approval in Northern Ireland has welcomed the knighthood awarded on New Year's Day to Dr. Thomas Houston, director of the laboratories in the Royal Victoria Hospital, Belfast. Dr. Houston was born in Coleraine, county Antrim, and studied in the old Queen's College, Belfast; he graduated in arts in the old Royal University of Ireland in 1890, and in medicine in 1895, and proceeded M.D. in 1899, after a collegiate and university career full of the highest honours. Later he obtained the University studentship in pathology, and was research scholar of the British Medical Association, 1902-3, and was appointed physician to the Ulster Hospital for Children and Women, Belfast, and also to the Forster Green Hospital for Consumption, and physician in charge of the department of haematology and vaccine therapy of the Royal Victoria Hospital, Belfast. During the war he served as temporary honorary major R.A.M.C. for three and a half years, and was mentioned in dispatches and received the O.B.E. He was early appointed joint lecturer in medical jurisprudence in Queen's College, and holds the same post now in the Queen's University of Belfast. With the great enlargement of laboratories in the new Royal Victoria Hospital, and the formation of several departments, such as biochemistry, he was asked to take general charge, and was made general director. He had given much time and trouble to their organization and equipment. Within the last few years, with Dr. Trimble, chief tuberculosis officer of Belfast, and Dr. Norman Graham, bacteriologist to the Belfast Corporation, he was sent to visit numerous places on the Continent, chiefly with the object of studying the latest treatment of consumption. Dr. Houston is one of the indefatigable quiet workers of the time. One, two, and even three o'clock in the morning saw him in his laboratories, not once or twice, but as a routine, with a band of followers whom he had infected with his zeal; and many of his pupils have already gained places of distinction. The fortnightly meetings in his laboratories at the hospital which he inaugurated are a source of delight and of great value to the medical staff and to those private friends who are privileged to attend; everyone makes some contribution to the work, and the encouragement and guidance to the younger members are of infinite service. The medical profession of Ulster feel an exceptional pleasure in the recognition of Dr. Houston's work, as it is due purely to his long and arduous devotion to scientific medicine, with independence of any political influence, to his valuable aid in guiding the lay authorities, and to his own lovable personality.

THE TREATMENT OF CHILDREN.

That veteran of medicine and sanitation and lover of childhood Sir John Moore recently delivered by request an inaugural address at the Meath Hospital, Dublin, on the treatment of children. During a long and busy life Sir John Moore has always found time for philanthropic work outside his strictly professional duties, and as a member of the voluntary Dublin Sanitary Association he has helped greatly to improve the health conditions of the capital. In 1872, when this association began its work, Dublin was notorious for its slums and the bad conditions under which the poor lived. Since then increased cleanliness of persons and dwellings has made typhus fever a scourge of the past, but yet much remains to do, for the housing question is still an acute one. Only ten years ago it was found on inquiry that the percentage of one-roomed tenements in Dublin was as high as 33.9, whereas the highest in England was 14.8, and in Dublin the average number of inhabitants of such tenements per room was 3.31. Such conditions have, of course, a very grave influence on infantile and puerile disease and death.

The lecturer did not fail to draw the appropriate moral from these figures and to stigmatize the death rate from diarrhoea and enteritis as appalling. Improvement in dairies and in the whole process of milk distribution must be looked to for a reduction of this mortality, as well as early and proper treatment of affections of the mouth, such as thrush, which has been shown to bear a distinct relation to subsequent enteritis. In reviewing the activities of the hospital as regards children, Sir John mentioned that the Meath Hospital has as yet only one children's ward—that named after a former surgeon, the Smyly Ward for surgical cases. He pleaded the necessity of more accommodation for both medical and surgical diseases and injuries of children, and commented on the unnecessary mortality and disfigurement caused by burns, generally the result of poverty and the non-provision of fireguards.

In the hospital year ended March 31st, 1926, there were treated in the wards 267 children of or under the age of 12 years, forming 16 per cent. of the in-patients. Forty-five of these were medical cases, without any deaths. Of the cases on the surgical landing, which includes the Josiah Smyly children's ward, there were 113 child patients and nine deaths, five of them from burns and scalds. This is a good record. The remainder of the 267 were treated in the emergency wards or the epidemic block, and included various injuries and infections. Tuberculosis, as Sir John says, is a terrible scourge. Nineteen of the children were admitted to the observation wards of the Tuberculosis Committee of the County Dublin County Council. Unfortunately for the Dublin children who suffer from surgical tuberculosis, the Tuberculosis Prevention Act (Ireland) of 1908 provides for notification of tuberculosis in certain prescribed forms and stages, "but no forms of tuberculosis shall be so prescribed [*sic*] save such as by reason of infective discharges are liable to communicate the disease to other persons." Obviously this clause shuts out nearly all cases of tuberculosis in children in the stages in which they are most amenable to treatment. Nevertheless, as before stated, nineteen tuberculous children were treated in the wards provided for the purpose in the Meath Hospital, one of the functions of which is to act as the county tuberculosis hospital. Dublin is not ill provided with convalescent homes for children, and in its nearness to the sea and to fine mountainous country it has advantages over London and some other capitals.

BIRTHS, DEATHS, AND MARRIAGES IN THE IRISH FREE STATE.

The annual report of the Registrar-General for the Irish Free State for 1925, just issued, shows reductions in the number of marriages, births, and deaths, as compared with the preceding year, and a large increase in the number of emigrants. The total for 1924 was 19,077, of whom 12,016 went to the United States of America. In 1925 the number was 30,302, including 26,546 to the United States, 1,861 to Canada, 1,076 to Australia, 290 to New Zealand, 110 to South Africa, 136 to India, and 223 to other countries. Marriages numbered 13,820, equivalent to a rate of 4.63 per 1,000 of the estimated population. This is 1,002, or 0.30 below the figure for 1924, and 0.45 below the average for the ten years 1915-24. Births numbered 62,069 (31,818 boys, 30,251 girls), equivalent to 20.8 per 1,000 of the population, being 0.3 above the average of the ten years. The rate in Northern Ireland was 22 per 1,000, in England and Wales 18.3, and in Scotland 21.3. Amongst the births registered were 682 of twins and 9 of triplets. Deaths numbered 43,650 (males 22,118 and females 21,532), giving a rate of 14.2 per 1,000 of the population. The mortality from all causes was 0.41 per 1,000 below that of 1924 and 1.30 below the average for ten years. The death rate from all causes in Northern Ireland was 15.74, England and Wales 12.16, and Scotland 13.39. Deaths from the principal epidemic diseases yielded a rate of 0.54 per 1,000. Deaths from all forms of tuberculous disease numbered 4,673 (2,307 males and 2,366 females). The total is equivalent to a rate of 1.57 per 1,000 of the population. The corresponding rates were: in Northern Ireland 1.67, in England and Wales 1.04, and in Scotland 1.10. The average total deaths from tuberculosis in the ten years 1915-24 was 5,580. The total for 1915 was 6,725, or at a rate of 2.19 per 1,000 of the population; this fell consistently to 4,468 (rate 1.48) in 1923, which was the lowest recorded in the Irish Free State. This was followed in 1924 by an increase

of 114, and a further increase of 91 in 1925. Deaths from cancer numbered 2,801, a decrease of 102 as compared with 1924. There was a distinctly upward tendency in the mortality from cancer in the years 1923 and 1924. The number for 1923 gave an increase of 8 per cent. on 1922; and 1924 gave a further increase of 6 per cent. on 1923. The mortality from cancer in the Irish Free State during the five years 1921-25—namely, 0.90 per 1,000—would appear to show a real increase of 32 per cent. as compared with the average annual rate (0.68 per 1,000) for the ten years 1901-10. In Northern Ireland the rate was 1.15 per 1,000, in England and Wales 1.34, and in Scotland 1.36. Of the total deaths, 6,356, or 14.6 per cent., were of children under 5 years of age, and 19,955 (45.7 per cent.) were of persons aged 65 or upwards. Deaths of persons aged 95 or upwards numbered 333, including 60 whose ages were returned as 100 or over; one of these was stated to be 115. Deaths of infants under 1 year numbered 4,216, equivalent to a rate of 68 per 1,000 births, as compared with 72 in 1924, and an average of 77 for the ten years 1915-24. In Northern Ireland infant mortality was 86 per 1,000 births, in England and Wales 75, and in Scotland 91. Deaths caused by violence numbered 816—113 less than in 1924, and 512 below the average (1,328) for the ten years 1915-24. Of the total, 88 were classed as suicides, 24 as homicides, and there was one execution; of the rest most were definitely due to accident. Eleven deaths were caused by poisons or poisonous gases, and 149 by burns or scalds; there were 126 deaths from accidental drowning, 25 due to firearms, and 100 due to injuries caused by crushing, including 53 (as compared with 46 in 1924) by motor-drawn vehicles.

Scotland.

EDINBURGH ROYAL INFIRMARY.

AT a recent meeting of the board of managers of the Royal Infirmary of Edinburgh it was intimated that Sir James Hodsdon and Sir David Wallace had been appointed representatives of the Royal College of Surgeons on the board of management. Dr. William Russell and Dr. John Orr had been appointed by the Royal College of Physicians, and Professor Harvey Littlejohn and Professor William Wilson by the Senatus Academicus of the University. A letter was read from the Royal Society of London asking for the nomination of a delegate for the celebrations to be arranged for the centenary of Lord Lister in 1927, and Dr. George Mackay, Convener of the Medical Managers' Committee, was appointed a delegate for this purpose.

SCARLET FEVER IN SCOTLAND.

In a bulletin for November, 1926, issued by the Glasgow Public Health Committee, it is stated that the death rate for the month (14.6 per 1,000) compared very favourably with the general death rate of 17.4 during the corresponding month of last year. This decline is ascribed to a lower death rate from infectious diseases, especially measles. The number of cases of scarlet fever certified was 605, as against 758 in October, so that this epidemic appears to be on the decline. The case mortality had been low—under 1 per cent.—although recently some cases of a more severe type had been admitted to hospital. These severe cases were treated with specific serum. An outbreak of scarlet fever has occurred at Musselburgh, and 28 cases were notified during the three days preceding December 14th. The outbreak had been traced to a contaminated milk supply, and was believed to be well in hand. An outbreak of scarlet fever has occurred also in Grangemouth; within five days 20 cases, all but four of them adults, were removed to the burgh isolation hospital; subsequently the notifications averaged six a day. The epidemic was chiefly limited to one part of the burgh, and the origin of the outbreak was subsequently traced to the milk supply from a local dairy, where a dairymaid was found to be suffering from scarlet fever, unrecognized by herself or her employers.

PURE MILK IN NATIONAL HEALTH.

At a meeting of Midlothian County Council, when the prizes gained in the recent clean milk competition were presented, Sir Robert Greig, chairman of the Board of Agriculture for Scotland, congratulated the council on its enterprise in carrying out this competition in collaboration with the Agricultural College. The increased consumption of milk would be of great advantage to the consumer as well as to the farmer. Sir Robert Greig presided at a meeting, on the same day, of the Edinburgh Women Citizens Association, when Mrs. Chalmers Watson, M.D., gave an address, in which she pointed out that the present pure milk campaign was part of a larger national movement in the interests of pure food. A great forward step had been made in the establishment of grades of milk, and the public now recognized that milk could be procured with a guarantee that it was clean and free from taint of tuberculosis; even the most expensive form of certified milk, selling at a shilling a quart, compared favourably with other animal foodstuffs, for a quart of milk was equal in nutritive value to a pound of steak or to nine eggs. It was essential for the public to recognize that the higher grades of milk necessarily involved increased cost. A herd entirely tubercle-free was costly, and a high standard of cleanliness required increased labour and laundry charges, while rich milk could not be ensured without an increase in the quantity and quality of the cows' food. Bottling on the farm, which was a guarantee of purity, was costly, and the charge for its transport was high. A sufficient number of farmers were now producing higher grades of milk, and the extent to which this great movement would proceed now lay in the hands of the public.

The committee on physical instruction and health of the Edinburgh education authority has received a letter from the Scottish Board of Health regarding an investigation into the nutritive value of milk for school children. It was proposed in Edinburgh to have four groups of fifty or sixty school children between 8 and 9 years of age, to whom certain quantities of milk and biscuits would be supplied during school hours for a period of about eight months. Records as to the height and weight of these children would be taken under the supervision of a woman medical officer appointed by the Scottish Board of Health, who would provide funds for the investigation. The education authority approved of the Board of Health's request on the understanding that the consent of parents would be obtained in the first place.

EDINBURGH CONGESTED AREA IMPROVEMENT.

A ceremony was held on December 22nd, 1926, at the New College Settlement, Pleasance, Edinburgh, to mark the completion of the first stage of a scheme for providing a gymnasium, play-hall, baths, and open-air playground in a highly congested district of the city. The New College Settlement has been in existence for some years, but developed into the Pleasance Trust in 1914. The population around the new buildings is estimated at 725 persons to the acre, and the activities of the Trust have resulted in a certain acreage of land being kept as an open area, while on other areas buildings of modern construction are being erected. A child welfare centre is included, as well as a covered games ground, and other buildings are to be erected for the needs of the adults of the district. A sum of nearly £11,000 is in hand, although more is still required to complete the scheme. In the child welfare centre a department for artificial sunlight treatment, under the control of Dr. William Robertson, medical officer of health for the city, has been installed, together with a roof garden from which a striking view of the Queen's Park and the Firth of Forth is obtained. Lord Murray, chairman of the Trust, delivered an address at the close of the ceremony, in which he said that the building was the first stage of a great scheme of which the Rev. J. Harry Miller was the mainspring.

THE CRIPPLE CHILD.

The report presented to the twenty-fourth annual meeting of the Edinburgh Cripple and Invalid Children Aid Society showed that the number of cases on the books

during the preceding year had been 685, while the society had cared for 2,070 children since its inauguration. Bailie T. G. Nasmyth said that a scheme for the establishment of an institution for the crippled child was under consideration; it would provide a central hospital on the outskirts of Edinburgh and affiliated clinics in various centres of the south-east of Scotland. Mr. Alexander Miles, F.R.C.S., in commending the society to the continued support of the public, said that the great majority of the cases with which the workers of the society had to deal were suffering from conditions which might have been prevented if matters had not been allowed to drift owing to want of an organization for dealing at an early stage with the diseases which caused crippling.

England and Wales.

Welsh National Medical School.

Another stage in the long conflict about the status of the Welsh National Medical School will be reached on January 14th, when a special meeting of the Court of the University of Wales is to be held in Shrewsbury to consider a draft charter for the incorporation of the Welsh National School of Medicine as an independent school of the University. Objection is taken to the proposal by the University College of South Wales and Monmouthshire, which proposes that the School of Medicine should be a unit of the College and not of the University as a whole. The College also proposes that the School of Medicine should be administered by a board of medicine, responsible, as it would seem, to the College Council, with a warden or provost, who would be subject to the control of the Board of Cardiff College. The College proposes further that the departments of anatomy and physiology should form parts of the Medical Faculty. The Council of the University in the charter now to be discussed adheres to its decision to make the Welsh National School of Medicine a separate body directly responsible to the University Council, but is willing to submit the question of the further position of the chairs of anatomy and physiology to a committee of experts, to be chosen by a small body representative of both councils. Under the council's draft scheme the president, who would be the head and chief officer of the Medical School, would be appointed by the University Court. The provost, who would be the principal academic and administrative officer of the School, would be appointed by the Council of the School, and might be one of the professors. The Council would consist of the president and provost (*ex officio*), fifteen members appointed by the University Court, three by the Cardiff Royal Infirmary, three by the professorial staff, and one by the Welsh National Memorial Association. Of the fifteen members appointed by the University Court six would be nominated by the University College of South Wales and Monmouthshire, of whom not less than two would be representatives of county councils or county borough councils, and one each by the University Colleges at Aberystwyth, at Bangor, and at Swansea. There would be two faculties—one of pure medical science, and the other of applied medical science.

Health of Liverpool.

Dr. A. A. Mussen, medical officer of health for Liverpool, in his annual report for 1925, estimates the population of the city for the year at 842,968. The birth rate was 23.3 per thousand, the death rate 14.1 per thousand, and the infantile mortality rate 99 per thousand births. No case of plague, small-pox, or typhus fever was noted in 1925. A number of women and girls contracted fur dermatitis through wearing cheap furs dyed with meta- or para-phenylenediamine so as to simulate beaver. There were 48 cases of enteric fever, of which 2 were paratyphoid A and 3 paratyphoid B. The cases of diphtheria were 1,504 and the deaths 106. The corresponding figures for scarlet fever were 3,561 and 93. The relatively high death rate and case mortality rate of these diseases during the last five years in the crowded central portions of the city are ascribed to the high proportion there of children of susceptible ages. The medical officer has recommended to the Port Sanitary and Hospitals Committee a scheme of co-operation with general practitioners for the prevention of diphtheria and scarlet fever. The family doctor will be asked to advise parents as to the value of protection for their children. Aided by the Health Department he will apply the Schick and Dick susceptibility tests to children over 5, the testing of younger children being thought needless, and he will be provided by the Health Department with the necessary prophylactic substances for administration to reactors. It has been observed in Liverpool that outbreaks of measles tend to recur at intervals of about ninety-two weeks. In years when the epidemic peak would be due in August, September, or October two maxima may appear, one before and the other after the expected date. In 13 out of 77 acute indigenous cases of encephalitis lethargica a possible association with a previous patient is believed to have been traced. Cases of puerperal fever during the year numbered 56, with 21 deaths. The cases of ophthalmia neonatorum were 734, the cures by the end of the year 673; no child was left with damaged vision. Over 200 open-fronted butchers' shops have been fitted with glass windows, so that all meat for sale is under cover. Among 5,587 milk samples from city cow-keepers 4.1 per cent. showed tubercle bacilli; among 10,303 samples from sources outside the city the corresponding percentage was 6.8. A food preparation described as chocolate eggs was found on analysis to contain quartz, zinc, lead, and other metallic fragments; the stock of the dealer was seized, and a fine of £20 inflicted. In the last five years over 8,000 dwellings have been erected in Liverpool, but the waiting-list of applicants for corporation houses contains 11,000 names. The numerous statistical tables and graphs in this report, extending back in some cases over a long series of years, are of great epidemiological value.

London Schools.

The Annual Report of the London County Council,[1] Volume IV, for 1925, deals with education. It is full of the details of the immense activities of the educational affairs of this collection of cities we call London. There are 960 schools with 665,000 children, 61 central schools with 20,000 pupils, 74 secondary schools with 31,000 pupils, 46 technical institutes with 55,000 students, 24 trade schools with 3,200 students, and besides these there are many continuation schools, evening institutes, and special schools. The work of medical inspection employs 25 full-time and 64 part-time doctors; these inspected 317,000 children in the year, and there were treated under the Council's scheme with local centres and hospitals 254,000 children. The total cost of the education service reached nearly thirteen million pounds in the year. Even the libraries of the elementary schools are on the same million scale, for there are no fewer than two and a half millions of books, not counting an additional quarter of a million on the shelves of evening institutes. And the books are used; each of those in the elementary schools went out on an average six times in the year—no mean record. The whole of the report is full of records of this great work in its various branches. Any one of them would be of sufficient interest to fill the space of a review. Perhaps the most interesting sections are to be found in the two appendices. Novel methods have been adopted to show the changes in London conditions. There are photographs of some of the elementary schools, and of some of the children in these schools, at different dates. Ninety-five per cent. of all the children of London attend the elementary schools; there are enough of them to replace in numbers the whole of the population of Manchester, or half the population of the Dominion of New Zealand. The very old buildings are all denominational or parochial schools; there are some very old ones still existing and in use. "The Blewcoat School, built in the year 1709," is the inscription on the oldest school in Westminster, and still in use; it was originally a charity school. St. Luke's, Chelsea, has had a continuous history since 1595, the present buildings dating from 1824. There is no common style in the old schools. Style did not arise

[1] Annual Report of the London County Council, 1925, Vol. IV: Education. P. S. King and Co., 14, Great Smith Street, Westminster. 1926. (Pp. 48. Price 1s.)

until school boards came into being in 1870. Since then London schools can be dated as clearly as feminine fashions. Those of the seventies were plain brick buildings of some dignity, but with interiors that would be abhorrent to modern educationists. The school building was made up of a series of huge classrooms, each for some seventy children and intercommunicating; indeed, there were often no corridors. Most of the children sat with their backs to the light, unless it happened to be in their eyes. In the second period, the late eighties, buildings were generous, even handsome, in style; there were flights of steps, pillared porticoes, gables, and fine brick and stone work. The interiors were an advance, since there were fine halls, better classrooms, but still too big, and corridor entries. But the lighting was severely cold, a northerly aspect for the rooms being thought best for work. There was one great advance, in the provision of playgrounds. To-day's buildings are a return to plain severity and utility, but there is a dignity of clean balanced mass which their immediate predecessors sometimes lacked. The interiors are the great change. A hall large enough to take the whole school, many and small classrooms which cannot take more than a certain number of children, with a sunny aspect so far as possible; good wide high windows, well arranged artificial lighting, blackboards well placed, ample cupboards for teaching materials, rooms for the head teacher, for the staff, for medical inspections, a practical workroom, and sometimes provision in the large playgrounds for open-air classes. The second appendix illustrates by photographs the changes in the conditions of the children in certain of the schools thirty years ago and now—that is, 1894 and 1924. Dr. Kay Menzies writes: "Quite definite medical conclusions can be drawn from the photographs on the last two pages. It must strike everyone that the children in the later photographs are brighter and more intelligent in appearance, infinitely better cared for, and happier looking. Taking a group of boys, the 1894 group presents great inequality in physical conditions, the types ranging from robust to very ill nourished, while the 1924 photograph shows a set of boys of average nutrition without any of the inequalities of the former group. Carriage and posture are deplorable in the earlier photograph, slack and loose postures [illegible] the later photograph the evidence is very apparent in the improved carriage and alert appearance. A very striking medical point is the absence of mouth breathing in the later group, while in the earlier group two of the nine boys are mouth breathers. These two groups of photographs of buildings, both exteriors and interiors, with the outdoor classes, and those of the children of 'then' and 'now' are well worth examining. But the conditions themselves need to have been seen for the amazing change that has come in the last thirty years to be appreciated."

Correspondence.

THE ABANDONED MENTAL DEFICIENCY BILL.

SIR,—In view of the misunderstanding which appears to prevail in certain quarters regarding the now abandoned Mental Deficiency *Bill*, perhaps you will be good enough to allow me to attempt to explain the purpose and scope of this measure.

It is apparently thought by some persons that the Mental Deficiency Act of 1913, if not actually designed to obtain control of individuals who are quite capable of looking after themselves, has at all events been used for such a purpose, and that consequently any amendment which would facilitate its working should be strenuously resisted. There could be no more mistaken view. The Act of 1913 was a long-overdue measure passed in the interests not only of the community, but also of defectives themselves, and it has not inaptly been termed "the charter" of the feeble-minded. Speaking from a large experience of the working of this Act, I have never known, or heard of, a single instance in which a person has been dealt with under it who was not in need of supervision. It should also be pointed out that, contrary to what is often thought, certification under the Act is by no means irrevocable. Every first order automatically expires at the end of a year, and each case must then be reviewed and, if considered necessary, another order signed. A further review takes place at the expiration of another year and subsequently at five yearly periods.

As a matter of fact, far from being applied improperly or too widely, circumstances have combined to interfere very seriously with the working of the Act, and to withhold from thousands of defectives the protection of which they are in need. As evidence of this I may state that while the total number of defectives in the country is estimated at approximately 174,000, about half of whom are in *urgent* need of care, the total number dealt with under the Act on January 1st, 1926, was only 36,815, of whom 15,733 were under supervision in their own homes.

There are two main reasons for this. One is the utter inadequacy of existing accommodation; the other is the wording of the definitions of the Act. According to the Act of 1913, the mental defect must have existed "from birth or from an early age." Personally, I have always contended, and taught, that the chief purpose of these words was to differentiate between arrested mental development and disorder or decay arising *after* the mind had attained to that degree of development which would enable the individual to transact the ordinary affairs of life, and that the words should be interpreted in this sense. But many magistrates, and some medical men, have placed a much narrower construction upon them; they have taken "an early age" to mean the first few years of life, and it is this which has led to considerable difficulty in the administration of the Act.

For instance, there are individuals in whom the defect, although undoubtedly of such a nature as to render them in need of care, supervision, and control, has not made itself evident until the years of adolescence. The increased demands of life, even of a simple one, have then rendered patent a deficiency which had hitherto been latent. There are other cases in which an arrest of mental development has actually been caused during early adolescence, as, for example, by encephalitis lethargica. There are yet others where no early history is obtainable. It is obvious that cases of this kind—and they are numerous—will be excluded from the protection of the Act by a narrow interpretation of the words "from an early age," and a recent Home Office Committee was so much impressed by this that it recommended that these words should be entirely deleted. In my opinion, however, such deletion, in the absence of any definition of mental defect, would have brought within the scope of the Act persons who were not really mentally defective and to whom it was not meant to apply, and I think the Minister of Health was wise in introducing a clause which, whilst doing away with the difficulty resulting from the original definition, yet made it clear that mental defectiveness was not disorder or decay of mind, but "arrested or incomplete" mental development.

The question has been raised as to the applicability of the new definition to adults. I am very definitely of the opinion that, with the exception of adults in whom the defect has been brought about before the termination of adolescence, the new definition would no more apply to adults than did the old one. Since mind reaches a stage of development which may be regarded as normal or adequate for the ordinary purposes of life before the termination of adolescence, it is clear that any change taking place *after* this is not mental arrest. Personally I should certainly object to any definition which extended the scope of the Act to cases of mental disorder or decay, which are already provided for by the Lunacy Act; but I am convinced that it is not intended to do this, and that the bill does not, in fact, do so.

It is important to point out that the definition of mental defectiveness in the bill must be read in conjunction with the definitions contained in the preceding clause. For a person to come within the scope of the Act the arrested or incomplete development of mind must be of such a degree as to prevent him from "guarding himself against common physical dangers"; or from "managing himself or his

affairs"; or be so pronounced as to necessitate "care, supervision, and control" for his own protection or for the protection of others.

In conclusion, there can be no doubt that the Mental Deficiency Act of 1913 is not only a sound measure of social reform, but that it is in the highest degree a humane measure. I find it simply amazing that any person who has read the Report of the Royal Commission of 1904, or who has any practical knowledge of mental defectives, or who is even really concerned for the welfare of the community, should obstruct a bill the sole purpose of which is the remedying of defects which experience has revealed in the original Act. I am convinced from the comments and letters which have reached me that workers who have spent years in endeavouring to improve the lot of the unfortunate mental defectives will view the abandonment of the bill with dismay.—I am, etc.,

London, W.1, Jan. 3rd. A. F. TREDGOLD, M.D.

ACUTE SUFFOCATIVE PULMONARY OEDEMA, CARDIAC ASTHMA, AND CHEYNE-STOKES BREATHING.

SIR,—During the past few months a number of cases have been reported from various sources of acute pulmonary oedema, which have been quickly relieved by hypodermic injections, of which morphine has been a principal ingredient. Most of these cases appeared to me, as I read them, to be cardiac in origin, and examples of what has commonly been called "cardiac asthma" which, though a dry variety exists, characterized by extreme air-hunger and by hyperpnoea, is very commonly accompanied by rapid and sometimes extreme effusion into the bronchi, and which, as Mackenzie has pointed out, is frequently associated with pre-existing Cheyne-Stokes breathing.

The general recognition that these cases can be relieved by morphine, with or without atropine, will save much suffering; for practitioners have often been afraid to give opium in such cases, for fear of locking up the fluid, which, however, is rapidly reabsorbed under the influence of the drug.

The objects of this communication are: first, to point out the connexion between these three conditions, all of which, in their severer phases, can be productive of an agonizing anoxaemia, and all of which can generally be relieved by morphine; and, secondly, to note that, where the cause is cardiac, and the attacks sufficiently severe to call for symptomatic treatment, the eventual prognosis is grave. Mackenzie said that patients did not survive the initial attack of cardiac asthma (usually nocturnal in incidence) for more than two years. My own experience has confirmed this, twenty-two months being the longest period I have noted, though I have two or three cases of less than a year's duration in which I hope that extra care, resulting from recognition of their plight, may possibly secure a longer tenure of life. But such patients (who often feel wonderfully well for weeks or even months at a stretch), must limit physical effort to a constantly low level to give themselves the best chance of what is at most a limited outlook.

Those interested in these matters will find several cases resembling some of those recorded in your columns, and observations on the effect of morphine on Cheyne-Stokes breathing, in a paper which I read at the Therapeutic Section of the Royal Society of Medicine three years ago, and which was reproduced in the *Lancet* (December 22nd, 1923, p. 1345), "On the use of opium in cardiac dyspnoea."—I am, etc.,

CLAUDE WILSON, M.D., M.R.C.P.

Tunbridge Wells, Dec. 20th, 1926.

CANCER RESEARCH.

SIR,—May I be allowed to supplement briefly Sir William Simpson's remarks (BRITISH MEDICAL JOURNAL, December 4th, 1926, p. 1080), with reference to the immunizing factor of lipase in cancer, by some further remarks bearing on the etiology of the disease? He recalls the observations of O. Rosenheim, and myself, that lipase in extracts of the pancreas, and in pancreatic juice itself, is separable into two parts, one ("co-enzyme") which is thermostable, and the other ("inactive lipase" or prolipase) which is destroyed by heat. Each part by itself has no fat-splitting action, but together become active.

The presence of a lipase (with other intracellular enzymes) in tumour cells has long been known. Although it may not be identical with that in the alimentary tract, the effect on fats is substantially the same. Presumably it is separable into two parts, as in the case of pancreatic lipase. In the limited quantity available this is difficult of proof. But (*a*) carcinoma tumour extracts prepared in various ways have long been shown to possess activating properties on inactive lipase, and can take the place of pancreatic co-enzyme. The fat-splitting action is, however, less, and compared with the activating action of normal tissue extracts generally, it is also less. The chemical agent responsible in cancer extracts is no doubt different from pancreatic co-enzyme. (*b*) Carcinoma extracts prepared in the same way as extracts of the pancreas by filtering through a Pukalls porous filter or Buchner's filter, show a similar preparation into two parts, filtrate and deposit, the latter being in the form of a fine powder. The filtrate (heated) activates pancreatic inactive lipase, but such activating action on the separated deposit itself was not shown, perhaps due to difficulties in collection of the very scanty deposit obtained in my experiments in 1922, owing to the limited amount of undegenerated carcinoma tissue usually available.

Bacterial vaccines (heated in the usual way) were found also to activate pancreatic inactive lipase, but in relatively small degree. To this property immunizing and therapeutic action was in part attributed in the treatment of certain specific infections, and the same indicated for heated cancer extracts and preparations in cancer. In short, by analogy with bacterial infections, without assuming a bacterial origin in cancer, the activator in cancer extracts seemed comparable roughly to *amboceptor*, in each case regarded as specific, and inactive lipase to *complement*. The view expressed (1913) was that cell proliferation in cancer might be due either to failure or upset of normal intracellular enzyme action with imperfect products of digestion in areas of the body affected, or to the presence of unusual enzymes (bacterial or otherwise) as stimulus.

In the very remarkable and arresting work of Dr. W. E. Gye and Mr. J. E. Barnard on the etiology of malignant new growths, it is shown that filtered and presumably cell-free tumour juice of Rous sarcoma (fowl) is separable into two parts. One part of the filtrate is inactivated by chloroform and the other by acriflavine. Each by itself is innocuous, but the two together, when injected into suitable fowls, produce a tumour. Briefly expressed, the result is attributed to an ultra-microscopic organism or virus, which is culturable, and an accessory chemical substance. Dr. Gye alludes to a labile chemical substance present in the filtrate rendered innocuous with chloroform, and in the virus rendered innocuous with acriflavine and other antiseptics. This agent or substance he regards as the essential factor, which he terms "specific factor," carried by the virus rather than by the chloroform-treated filtrate. It is difficult to avoid the suggestion that the labile chemical substance alluded to by Dr. Gye is of a similar nature to inactive lipase, and that it is activated by its own chloroform-treated filtrate or co-enzyme.[1] In his recent paper Dr. Gye notes that the agent or substance is sensitive to heat. Nevertheless the heated filtrate still retains its power in conjunction with virus to produce a tumour. This brings the inactivated filtrate into line with the heated cancer extracts and filtrates with activating properties on pancreatic inactive lipase, which I have described. If this aspect is correct, the thermolabile substance may be regarded as part or constituent of an unusual lipolytic enzyme present in either virus; or cancer cell (developmental; trophoblastic or chorionic originally put forward by the late J. Beard, 1905), which in each case is activated by its own co-enzyme; or that some other chemical irritant or stimulus impairs the lipolytic enzyme activity of the normal cell.—I am, etc.,

J. A. SHAW-MACKENZIE, M.D.Lond.

London, Dec. 23rd, 1926.

[1] *Journ. of Trop. Med. and Hygiene*, xxviii, p. 297, 1925.

A BACTERIOLOGICAL THEORY OF CANCER.

SIR,—I am authorized to communicate to you the following hitherto unpublished information concerning the researches of Dr. Carl Spengler of Davos Platz into human cancer.

In 1909 the late Professor Kocher of Berne sent to him for specific treatment certain cancer cases which had been operated upon and which had relapsed and were no longer operable. From four of these cases he isolated a Gram-positive bacillus which formed ovoid spores, and in the presence of body cells replaced the cell contents with their spores, and so with the limiting surface of the body cell formed spore sacs. He never had any doubt that this micro-organism is an essential cause of cancer.

He grows it upon the following medium: somatose Beyer 5 grams, peptone Chapoteaut 5 grams, sodium chloride (pure) 5 grams, sodium carbonate crystals 2¼ to 2½ grams, glycerin 60 c.cm., water 1,000 c.cm., with and without 1/2 per cent. glucose, with and without agar. From one of these cancer cases, on glucose agar, with repeated subcultures, the symbiotic growth of cancer cells and this micro-organism flourished for fifteen months before the cellular element died out and a pure culture of the micro-organism remained. He noted that when a loopful of human adult blood was mixed with a pure culture the blood platelets proliferated, and some would swell up and become nucleated; while the blood of a young, healthy infant, and the blood of an elderly person who had been treated with a vaccine made from this bacillus, did not give this result.

Last July he experimented by adding, after antiseptic treatment, the cells of pulmonary sputum, also the surface cells of the skin from the back of the hand, also a mixture of these skin cells and human blood, to a pure culture of this bacillus on solid and in fluid media. In every case he got proliferation of the cells; and after proliferation the cells would be entered by the bacilli and spores formed inside the entered cells, so creating the appearance of spore sacs. This change was most rapid and most pronounced with the sputum cells. He notes that when this bacillus is grown in culture with human body cells, those cells tend to become Gram-positive. He knows of no other micro-organism with which any of these results can be obtained.

He notes that when a pure culture of this bacillus is raised for a moment to about 95° C., and at once cooled, it still causes cell proliferation, but no longer destroys the proliferated cells, and that this heat-treated culture when injected into a rabbit produces a larger cancer tumour than the same quantity of normal culture.

Since the commencement of these researches Dr. Spengler has been treating his cancer patients with immune substance taken from the blood of animals immunized with this bacillus, or with a vaccine made from this bacillus, or both. During the past three months he has been studying the conditions which vary the malignancy of cancers caused by this micro-organism, with a view to increasing the efficiency of its vaccine. And he now calculates on arresting cancer formation in inoperable cases within two weeks of commencing treatment, and on getting rid of the tumour formed, by further treatment.—I am, etc.,

December 25th, 1926. J. BANCROFT ANDERSON, M.D.

PHARYNGEAL DIVERTICULA.

SIR,—In the discussion on my paper on "Pharyngeal and oesophageal diverticula," published in the BRITISH MEDICAL JOURNAL of December 18th, 1926, Dr. Irwin Moore questioned the propriety of including in the records of pharyngeal diverticular aeroceles the case published by Godlee and Bucknill in the *Lancet* of 1901 under the heading "A pharyngeal pouch of large size removed by operation." Dr. Moore asserted that "this case appeared, however, to have been wrongly described by them; it was undoubtedly a 'laryngocele,' since the sac contained air and its origin was laryngeal." Godlee and Bucknill, however, who were not unaware that some aeroceles in the neck had been stated to arise in the larynx, asserted in the concluding paragraph of their paper that their "pouch was obviously of the pharyngeal variety," and it appears to me that the balance of evidence detailed by them is strongly in favour of that view and against the unproved and unprovable dogmatic assumption of Dr. Moore.

There are two varieties of cervical air sacs which may pass through the thyro-hyoid membrane, one of which often passes some considerable distance upwards to open into the pharynx and on the palato-pharyngeal fold, and the other passes more or less directly into the ventricle of the larynx. The track of the former upwards may be hard to trace, whereas the latter, being adjacent and direct, should be quite easy. In Godlee and Bucknill's case they were unable to trace the route of the diverticulum beyond the thyro-hyoid membrane, but they concluded that the internal orifice was in the pharynx, and probably at the most usual site on the posterior faucial pillar, for the following reasons:

1. A laryngoscopic examination showed no abnormality in the larynx. [This negative finding is not definitive, of course.]
2. On squeezing this lateral air sac "an uncomfortable sensation was experienced by the patient, which shot up to the ear and lasted for several days." [This was very much more suggestive of a pharyngeal than a laryngeal lesion, it appears to me.]
3. For three years "swallowing had become difficult and painful until at last he could only swallow liquids." [Tumefaction due to inflation of the tissues of the left faucial pillar and adjacent side of the pharynx would account for the dysphagia. We have here a deglutitory symptom rather than a respiratory one.]
4. The swelling in the neck "reached upwards to a point above and behind the angle of the jaw." [This observation, though compatible with a pharyngocele, does not absolutely exclude the diagnosis of a laryngocele, of course.]
5. Microscopic examination of the wall of the sac showed the presence of glands "representing in every detail of their structure a mucous salivary gland," and they add that such glandular structure of the salivary variety have been found "in several cases" of pharyngocele. [The presence of these glands seems to me to be distinctly suggestive of a pharyngeal origin.]

Against the cumulative evidence of these several points we have Dr. Moore's single stated objection to the pharyngeal diagnosis—namely, that the "sac contained air and its origin was laryngeal." The statement that the sac contained air in no way excludes a congenital lateral pharyngeal pouch any more than does voluntary inflation, and the assertion that its origin was laryngeal because the sac was air-filled is a non sequitur.

Dr. Irwin Moore is admittedly an authority on the subject of laryngoceles, and I should be the last lightly to brush aside any really cogent reasons he can suggest for regarding the case so carefully and learnedly recorded by Godlee and Bucknill as originating in the larynx rather than the pharynx.—I am, etc.,

WILLIAM HILL.

London, W.1, Dec. 23rd, 1926.

MIGRAINE AND ACETONURIA.

SIR,—I have been interested in the discussion in your correspondence columns regarding acetonuria and migraine. I have had a case under my care for the past eighteen months—a policeman, aged 30, who suffers from periodic attacks of vomiting, constipation, anorexia with severe headache, and visual disturbances.

His first attack was several years ago, and they have been repeated at three-monthly intervals since then. When I first saw him during an attack I diagnosed cyclic vomiting from his history, symptoms, and presence of acetonuria. I treated him dietetically on a fat-free, principally carbohydrate diet, and medicinally with routine calomel followed by Glauber's salts, and with sodium bicarbonate. This treatment merely prolonged the interval between his attacks.

During his next illness I noted that the visual disturbance was more prominent (especially limitation of the visual field), but the headache, although severe, was bilateral. This new development, coupled with the age of the patient, made me doubt the diagnosis of cyclic vomiting,

although acetonuria was again present in the acute stage. I therefore sent the patient to the Edinburgh Royal Infirmary, out-patient department, where he was examined, and the consulting physician wrote me saying that, while he would not like to rule out the possibility of cyclic vomiting, I should watch the patient carefully for migrainous symptoms. The next attack confirmed the diagnosis of migraine, and the patient informed me that periodic headache was common amongst his progenitors on the maternal side.

Finally I sent him to the Edinburgh Royal Infirmary as an in-patient under the care of Dr. Chalmers Watson, where, I have no doubt, he was thoroughly treated for alimentary auto-intoxication. He resumed duty about four months ago and seems to have derived great benefit from the treatment.

I found that during an attack large doses of sodium bicarbonate and the exhibition of cannabis indica gave the greatest relief.—I am, etc.,

ARCHIBALD PENMAN,
Police Surgeon.

Stirling, Jan. 1st.

POST-OPERATIVE RADIATION IN CANCER OF THE BREAST.

SIR,—There are so many points for discussion in a consideration of the technique and results of post-operative breast cancer radiation that it is more suited to a pamphlet than a letter. As, however, Mr. G. Gordon-Taylor is reported (December 11th, 1926, p. 1097) as having said that "he had made an extensive trial of post-operative *x*-ray treatment; he had found that the prognosis was rendered worse, and had therefore abandoned it," perhaps I may be allowed to say that though he may have had bad results a number of years ago, after radiation inadequate as to area covered and method of application, and deficient in penetration, I do not find his conclusion in any way justified by analysis of the 44 cases he has referred to me at the Middlesex Hospital in the years 1921 to 1924 for "prophylactic" treatment. So far as my notes show, of the 44 patients (3 are not fully traced) 25 (=56.8 per cent.) have done well, and 16 have died. Of these 16, 6 had only *one to three treatments; 2 were sent after incomplete* operations; 1 was only 23 years of age; 2 died of recurrences internally within a few months of operation; and 1 was reported to have died of "heart failure." An important feature of Mr. Gordon-Taylor's series was that the average time that elapsed between the operation and the commencement of the radiation was the unusually long period of just over four months, some patients coming for so-called "prophylaxis" six and eight months or more after operation.

Analysis of the cases operated on by Mr. Gordon-Taylor in successive years, and then referred to me, shows that the one patient referred after operation in 1920 did badly; of his 1921 group all the 4 did well; of his 1922 patients 9 did well and 4 badly; of the 1923 ones 10 did well and 5 badly; whereas of the 1924 group 5 did well and 6 badly. Perhaps this last unfortunate year led Mr. Gordon-Taylor to conclude, I hope not finally, that radiation makes the prognosis worse. But of these 6 bad results, 1 patient had had *an incomplete operation; 1 coming three months after* operation was already too ill to attend further; 2 coming four months after operation showed signs of multiple recurrences in three or four more months; and 1 coming a month after operation was dead with metastasis seven or eight months after the operation. Thus analysis leads to the conclusion that in the year 1924 an exceptional number of severe cases had been referred for "prophylactic" treatment.

Considering the number of advanced cases referred, indeed, the result, as known to date (not yet three years), of 56.8 per cent. well, far from being a bad result is quite favourable, comparing well with Anschütz's 62 per cent. free from recurrence at three years in Group II (Steinthal) cases, with a similar medium-voltage technique. Forssell and others have reported similar figures with similar techniques; and thus the value of a prolonged medium-voltage prophylactic course appears to be established, giving better results than those generally found after operation alone in similar types of cases.

The high-voltage or "intensive" technique, as generally applied, has led to poor results in several clinics where it has been applied to prophylactic work; but by a modification in method, such as the "glancing" technique of Holfelder, good results are being obtained, as by obliquely directed rays, so to speak skimming the chest wall, the surface can be efficiently radiated without the risk to the patient of damaging the lungs, or giving rise to excessive general effect and lowered resistance by massive radiation of the blood in the heart and lungs.

Alternatively a medium-voltage pre-operative and post-operative scheme may be followed with apparent success, as at the New York Memorial Hospital. Time will show which of these alternative techniques is likely to lead to the best results.

I wish, however, without further discussion of the question, to dissociate myself from the bad results which have led Mr. Gordon-Taylor—unfortunately, I think—to abandon prophylactic radiation.—I am, etc.,

J. H. DOUGLAS WEBSTER.

London, W.1, Dec. 24th, 1926.

WILLIAM CULLEN IN GLASGOW.

SIR,—In the article on "The Edinburgh Medical School" in your issue of January 1st (p. 21) it is stated that Cullen "had removed to Glasgow, where he had delivered lectures on medicine and chemistry." This seems an inadequate tribute to this great figure of the eighteenth century. It is on record that he delivered in Glasgow lectures on botany, materia medica, and anatomy. He was lecturer on chemistry in the University from 1747 till 1755, and lectured on medicine in the same place from 1744 till 1751, when he was appointed to the Regius chair in that subject. In each of these University appointments he was succeeded by Joseph Black, who, like him, was transferred to Edinburgh.—I am, etc.,

GEORGE A. ALLAN.

Glasgow, Jan. 2nd.

ANTIGENS FOR THERAPEUTIC IMMUNIZATION.

SIR,—In your issue of December 25th, 1926 (p. 1242), Dr. Geoffrey Shera reports unfavourably upon the use of immunogens. This he is perfectly entitled to do. We sincerely wish that all physicians were as anxious to publish their results. Dr. Shera would then have found himself in a small minority as regards immunogens.

But Dr. Shera seizes a wholly inadequate opportunity to impute to us unworthy motives. "Anxiety to sell while the going is good can have only one result . . ." We are advised that this is libellous. We are quite confident that the medical profession at large entertains a higher respect for our intelligence, quite aside from any question of morality, than such a policy would connote.

We have made no claims regarding the immunogens but such as can be substantiated in the laboratory. Physicians generally will, no doubt, have due regard for the credentials of these products, and will perhaps share our difficulty in appraising the motive for Dr. Shera's "broadside," notwithstanding that he is interested in the preparation of autogenous vaccines for those who may require them.—We are, etc.,

PARKE, DAVIS AND CO.,
H. J. Fisk, European Manager.

London, W.1, Dec. 29th, 1926.

THE PUBLIC, THE DOCTOR, AND THE MASSEUSE.

SIR,—The medical profession in general, and electrotherapists in particular, are to blame for the state of affairs which Dr. Murray Levick describes (December 11th, 1926, p. 1142). In answer to a question in the House of Commons some time ago, the Minister of Health stated that if any evidence were produced of the dangers of ultra-violet ray treatment by unqualified practitioners he would investigate the matter. Why was this challenge not taken up? Was it because there are no such dangers, or

was it because of apathy on the part of the qualified practitioners? An article in the journal of the Massage Society in which the author (unqualified) boasted of having treated a case of pulmonary tuberculosis should have been almost sufficient to convince the Minister of the dangers of uncontrolled ultra-violet practice. Other similar cases would not be difficult to collect.

Apart from the dangers of ultra-violet treatment, there is sufficient evidence to show that the public is being "humbugged" on an unparalleled scale. In many instances the treatment is not by ultra-violet rays at all—but that, if more free from danger, is no less "humbug." On inquiry from a barber recently what the big lamp standing in the corner was, I was informed that it was his artificial sunlight apparatus. He added voluntarily that he had not treated cases of rickets, but that he was treating many cases of alopecia and also nervous women. Needless to say, the lamp was not an ultra-violet lamp at all; it was merely a lamp intended for giving radiant heat. I know of two masseurs who were using little high-frequency apparatus for ultra-violet treatment. To their credit be it stated that they were under the honest impression they were using ultra-violet apparatus. Instances of such abuses could be multiplied a thousand times. Legislation, however, would be extremely difficult to devise, and still more difficult to enforce, particularly as some of the leading authorities have advised the installation of ultra-violet plants at public baths and so on.

There is, of course, little danger to the normal healthy individual in an occasional ultra-violet ray bath, but there is as much difference between ultra-violet treatment of this nature and a course of treatment for a definitely pathological condition, as there is between a normal individual taking iodized salt to prevent goitre and the expert physician treating exophthalmic goitre with iodine. Both the former are ultra-violet therapy as both the latter are iodine therapy, but the technique and the care necessary are as wide apart in the former as they are in the latter.—I am, etc.,

London, W.1, Dec. 20th, 1926. M. WEINBREN.

THE CHOICE OF A LIFE INSURANCE POLICY.

SIR,—While not wishing to overlook the excellent help which the Medical Insurance Agency has rendered to medical charities, there appear to be certain well founded objections to the advice of any such agency in questions of life assurance.

1. Some life offices have shareholders, some are mutual. It is at once apparent that a policy with a mutual office is likely to be the better bargain.

2. An insurance agency is debarred from recommending a mutual office as no agency commission is paid.

I have been to some pains to compare the premiums of a good many offices. I have in mind one great mutual office whose financial stability I imagine nobody would question. The premiums for non-participating whole-life policies are absolutely rock-bottom prices. Why, therefore, pay more? I am not forgetting the allowance made by the Medical Insurance Agency of part of the commission. But even taking this into account, I believe that one can find the best terms for any life policy in the tables of one or other of the great well established mutual offices.

On the other hand, I should say that the "doctor's motor policy" appears altogether excellent.—I am, etc.,

Derby, Dec. 17th, 1926. A. ERNEST SAWDAY.

*** We submitted this letter to Mr. Ferris-Scott, F.C.A., Secretary of the Medical Insurance Agency, who has been good enough to write the following letter of comment:

Dr. Sawday, while not unmindful of the help afforded to medical charities by this Agency, offers some friendly criticism, to which I find it a pleasant duty to reply.

In commenting upon the existence of both mutual and proprietary companies, Dr. Sawday says: "It is at once apparent that a policy with a mutual office is likely to be the better bargain." This statement covers ground which is, to say the least, controversial, and I submit, with all respect, that this point is not capable of such summary dismissal. Many problems affecting organization and management—skill in which is not confined to the mutual offices—are involved. Moreover, a comprehensive record of the past achievements of the companies in these two main groups entirely fails to indicate any such obvious superiority as Dr. Sawday suggests.

The fact is that the liability represented by dividends to shareholders can all too easily be exaggerated in the public mind.

Under life assurance the contracts extend over a considerable number of years. To select, therefore, a company—no matter how strong—which is to-day offering the lowest rate of premium and, as Dr. Sawday appears to suggest, to invite our members one and all to effect policies therein, would attribute to the Committee of the Agency a gift of prescience it does not claim to possess. We prefer to follow the example of the Government when establishing the Federated Superannuation System for University Teachers, and to approve a group of carefully selected companies. Under that group are both mutual and proprietary companies, and the Committee is constantly revising the list in accordance with the latest information, as to security, bonus prospects, and rates of premium, at its disposal.

As regards his second point, Dr. Sawday is under a misapprehension in thinking that mutual companies do not pay agency commission; the majority of them do.

The following question is also asked: If a great mutual office quotes premiums which, for non-participating whole life policies, are "absolutely rock-bottom prices," why pay more? The argument here implied is based on cost, and on cost alone. The answer lies in the fact that there is one cheaper type of policy which, incidentally, this Agency does not weary of recommending—namely, a with-profit policy in a company with a good bonus record, based upon solid past achievements. Strength is lent to this reply by the fact that the strongest advocates of the non-profit policies to which Dr. Sawday refers themselves state that with-profit policies are more attractive still.

To sum up on general lines: It appears to the Committee that while every care should, of course, be taken in the selection of the office, yet a point of much more immediate importance to the intending assured is the choice of the policy which by its nature and conditions best fits his individual needs. The aim of this Agency is, by giving unbiased advice, to assist its members to make the best choice possible in a given set of circumstances, and our daily post-bag affords us very solid reasons for believing that our efforts in this direction have not been unsuccessful.

It is perhaps too much to hope that our advice has invariably turned out to be the best possible, but we do claim that no member has been allowed to effect a policy except on liberal terms and in a first-class company, and further, that our advice has always been given without fear or favour.

B.M.A. House, Tavistock Square, W.C.1, Dec. 30th, 1926.

The Services.

HONORARY SURGEON TO THE KING.

MAJOR-GENERAL F. H. G. HUTCHINSON, C.I.E., I.M.S., has been appointed Honorary Surgeon to the King in succession to Major-General Sir Robert C. Macwatt, C.I.E., I.M.S., who has retired.

DEATHS IN THE SERVICES.

Deputy Inspector-General Henry Nanton Murray Sedgwick, R.N. (ret.), died at Southsea on December 23rd, 1926, aged 86. He was the son of Dr. Samuel Sedgwick of Antigua, and was born on that island in 1840. He was educated at King's College Hospital, taking the M.R.C.S. and L.S.A. in 1862. Entering the navy in the following year, he soon after served in H.M.S. *Octavia*, flagship on the East Indies station, and during her commission had to deal with a severe epidemic of small-pox on the ship in the Persian Gulf and Bombay. He then served in medical charge of the naval brigade during the Abyssinian war of 1868, when he was mentioned in dispatches, and received the medal and also a special promotion. In 1873, while serving on H.M.S. *Salamis* on the China station, his services were lent to the Japanese Government to organize measures for the treatment of venereal disease. In 1882 he was fleet surgeon of H.M.S. *Inflexible*, under Captain (afterwards Lord) Fisher, and served at the bombardment of Alexandria on July 11th, 1882, receiving the Egyptian medal with a clasp, the Khedive's bronze star, and the Order of the Medjidieh, 3rd class. He retired in 1892 with the rank of deputy inspector-general.

Obituary.

T. S. P. STRANGEWAYS, M.A.(HON.)CANTAB., M.R.C.S., L.R.C.P.,

Huddersfield Lecturer in Special Pathology, University of Cambridge; Director, Cambridge Research Hospital.

IT was with deep regret that we had to announce last week the death of Dr. Thomas Strangeways Pigg Strangeways, at Cambridge on December 23rd, with symptoms pointing to haemorrhage into a cerebral tumour.

He was born on December 28th, 1866; his original surname was Pigg, which he changed at the time of his marriage. In 1890 he joined St. Bartholomew's Hospital, where he gained the Matthews Duncan gold medal in 1895, and obtained the diplomas M.R.C.S., L.R.C.P. in the following year. His vivid imagination soon drew him on to the investigation of problems of etiology connected with disease, and left him little time for private practice. His devotion to his work was so altruistic that, although he had a consulting-room in Harley Street, he neglected opportunities for personal gain, and many fees which should have come into his pocket found their way as subscriptions towards the expenses of research. While still a student at St. Bartholomew's he came under the notice of Professor Kanthack, who recognized in him the attributes of the truly scientific worker. He was appointed assistant curator to the museum, and collaborated with Kanthack in early contributions to the *Journal of Pathology and Bacteriology* and the *Transactions of the Pathological Society*.

In 1897 he followed Professor Kanthack to Cambridge, where he became demonstrator of pathology, and in 1905 was appointed to the newly created post of Huddersfield lecturer in special pathology, the endowment for which had been collected by Professor Woodhead. In 1900 he was given the honorary degree of Master of Arts, and during the war he was an inspector of military pathological laboratories.

Strangeways always maintained that the best way to study disease was to have cases for investigation under the same roof as the laboratories. In 1906 his ideal was realized by the opening of the Cambridge Research Hospital, which he planned and of which he was director until his death; this scheme was made possible largely through the generosity of Sir Otto Beit. The disease chosen for study was chronic arthritis, and for many years he worked incessantly at this in close contact with his patients; as a result of this work he published several papers and evolved a classification of types which brought some orderliness out of a mass of confusion. By 1912, when the new hospital in Hills Road was opened by another generous supporter, Sir Charles Brown of Preston, Strangeways had already notes of 4,000 cases of rheumatoid arthritis. His museum of arthritic joints was second to none, and consisted of some 2,000 specimens, all of which he had himself carefully dissected and mounted. Many of these were sent to him from distant parts of the world. Although much good spade work was done, he realized that the etiology of this disease had not yet been worked out, and that it was essential that more should be known about the physiological processes of growth in order to throw light on the problems of inflammation. He decided, therefore, to study the unit of life—the cell itself—much in the same way that the chemist turns back to the atom or the physicist to the electron. He therefore began an intensive study of tissue culture. Many have heard of the Research Hospital, Cambridge, but few realize the nature of the work that is carried on within its walls, and the important bearing that this work is likely to have on medicine in the future. At the time of his death he had five whole-time workers assisting him who were investigating the physiology and pathology of growth from various aspects. Some light was thrown on the problem of differentiation of tissues by such experiments as the growing *in vitro* of a complete eye or of a limb after their excision from the embryo in rudimentary form. Other work is being done on the metabolism of the blow-fly during metamorphosis, from which also it is hoped that valuable information will be gained about the differentiation of tissues. The connexion between the study of cell growth and cancer is not far to seek, and another large and important part of his work was in connexion with this disease. His interest in the effects of x rays on cells grown *in vitro* attracted to himself a group of men at St. Bartholomew's Hospital who have been working in close collaboration with him during the last five years. The object of this side of the work was to elucidate the problems connected with the disappearance of malignant tumours under the influence of radium and x rays.

At the Annual Meeting of the British Medical Association held in Liverpool in 1912 Strangeways was Vice-President of the Section of Pathology; and at the Cambridge meeting in 1920 he was Vice-President of the Section of Pathology and Bacteriology, and took an active part in the organization of the pathological museum. He was a good teacher, and had the gift of communicating his enthusiasm to others. His manual of *Clinical Pathology and Practical Morbid Histology* was widely read by students, and passed through seven editions.

Strangeways lived in the simplest manner, and his family life was an example of true happiness. He married Dorothy, daughter of the late E. A. Beck, Master of Trinity Hall, Cambridge, who survives him with seven children.

We are indebted to a colleague and friend for the following personal appreciation:

It is difficult to convey adequately a true conception of his character. To the superficial observer he seemed to be retiring and shy, and sometimes showed a singularly brusque manner. In reality he was very different, and the mistaken impression was entirely due to his deafness, with which he had been afflicted from the commencement of his career. When once he realized that a neighbour was sincere he was ready to throw off his assumed cloak and to offer him his complete confidence. It was at such times that one realized the breadth of his imagination and the vista of ideas which led and directed him in his work. When engaged on some investigation his enthusiasm and perseverance were alike remarkable, and sleep and food became secondary matters, which could be for the time entirely ignored. Visitors he always welcomed, provided they were genuinely interested and did not visit his laboratories out of mere curiosity; insincerity or sham he hated with an intense hatred. He frequently deplored the amount of published work which was printed before its validity had been established beyond all doubt, and in his own work he would go to great pains to establish or illustrate his point of view. In the last of a series of lectures which he delivered before the University he dealt with the subject of death and immortality. He illustrated the indeterminate character of death in point of time by cultivating and actually causing to grow cells derived from mince bought from a local butcher. His capacity for work was enormous, and he often likened the joy of tackling a problem to that of a mountaineer who, having reached one peak, sees many others still in front of him to climb.

SAMUEL CRAWSHAW, J.P., M.B., CH.B., M.R.C.S.,

Late Chairman, Ashton-under-Lyne Division.

WE regret to announce the death, on November 30th, 1926, of Dr. Samuel Crawshaw in his 67th year. He had practised in Ashton-under-Lyne for over forty years, but heart trouble of many years' duration had necessitated his retirement from active work in the previous March. He received his medical education in Manchester, and after obtaining the diploma M.R.C.S.Eng. in 1883 he graduated M.B., Ch.B.Vict. in 1891.

During the early nineties Dr. Crawshaw, in spite of his increasing practice, found time to interest himself in the British Medical Association, in the reorganization of which he was one of the most prominent and hard-working leaders. In his historical survey of the constitution and government of the British Medical Association Dr. J. C. McVail referred in detail to the active and valuable work of Dr. Crawshaw (JOURNAL, 1924, vol. i, p. 1053). He was a member of the Lancashire and Cheshire Branch Council from 1901 to 1910, 1919 to 1920, and 1925. He was

secretary of the Section of Ethics at the Annual Meeting at Manchester in 1902, and from 1919 to 1920 he was chairman of the Ashton-under-Lyne Division and a member of the Representative Body; he was also a member of the Executive Committee from 1915 to 1924. He was appointed secretary of the Manchester Medical Guild in 1899, and as secretary of the Committee on Organization established by the Manchester Conference of 1900 he attended many meetings in all parts of the country without neglecting the work of his practice. This, however, proved too much for him, and he had to relinquish the secretaryship later in the year. Sir Jenner Verrall, speaking at the representatives' dinner at Bradford, July, 1924, on the occasion of the twenty-first anniversary of the present constitution of the Association, referring to the initiation, progress, and perfection of the Representative Body, said that the idea of such a body began in the minds of two or three people, but in one in particular, Samuel Crawshaw of Ashton-under-Lyne. Crawshaw realized that this thing had to be, although, of course, he did not realize the form it would take at first. It was Crawshaw who set the ball rolling. It was not so difficult to pat the ball along once it was started.

Dr. Crawshaw's energy at this time was amazing, but he paid for it later in breakdowns of health. He was president and vice-president of the Ashton District Nursing Association, and later became a trustee. From 1915 to 1920 he was honorary physician to the Ashton and District Infirmary, retiring under the regulations at the age of 60. He was generous to a fault, and gave to the poor a large percentage of his income. In 1915 he was elected as a Liberal member of the Ashton Town Council, and served there till 1925, taking a very active interest in the formation of the child welfare centre. His deep interest in infant mortality then led him to study the housing question, the smoke abatement nuisance, and the pure milk and food supply. At this time he was also serving on the Lancashire Panel Committee, and in 1921 he was made a justice of the peace, serving on the bench until his retirement. All these demands on his time and energy began to tell on his health, and a few years before his death he was advised to confine himself to professional duties, which in themselves were quite onerous. He was an accurate diagnostician and no trouble was too great to take on behalf of his patients; consequently he was much loved, and his death will be widely felt as a personal loss. Through all his work and anxieties he was most ably seconded by his wife, who, with his two sons, survives him.

The MEDICAL SECRETARY writes: The death of Dr. Crawshaw makes a sad gap among those who were in at the inception of the new constitution of the Association. Those of us who were at the memorable meeting called by the Manchester Medical Guild in 1900 gratefully remember him as the originator of that conference, and the man who did nearly all the hard work in connexion with it. He it was who focused the general discontent among the younger medical men in the country about the constitution of the British Medical Association, its lack of local unit organization and of democratic control. It was the Manchester conference which brought matters to a head. When the Council of the Association appointed the Constitution Committee, whose efforts resulted in the present constitution of the Association, Dr. Crawshaw would undoubtedly have been a member had he so desired, but the pressing claims of duty at home made him decline to take any part in the central work, and he thus never obtained the publicity and prominence to which his work and personality might well have entitled him. But nobody rejoiced more than he did when the new constitution came into operation, and so long as his health lasted he was a tower of strength to the Association in Ashton-under-Lyne. His was a very modest and lovable personality, whose simplicity and sincerity of character impressed everybody with whom he was brought into contact. Those of us who have ever been privileged to work with Dr. Samuel Crawshaw will join with his colleagues in Ashton-under-Lyne in sympathy with Mrs. Crawshaw and her family.

LLEWELLYN POWELL PHILLIPS, M.A., M.D., F.R.C.P., F.R.C.S.,

Emeritus Professor of Medicine, Royal School of Medicine, Cairo.

We regret to announce the death of Professor L. P. Phillips, at the age of 55, on New Year's Day, at his residence in Kasr-el-Doubara, Egypt, after a long illness.

Llewellyn Powell Phillips, only son of the late James Mathias Phillips, M.D., of Cardigan, was born at Taibach, South Wales, on July 28th, 1871. From Epsom College he went to Caius College, Cambridge, in 1889, obtaining first-class honours in Part I of the Natural Sciences Tripos of 1892, and then entered as a student at St. Bartholomew's Hospital. He qualified as M.R.C.S., L.R.C.P. in 1894, took the M.B. and B.Ch Camb. degrees in the following year, and in 1897 obtained the diploma of F.R.C.S.Eng. In 1903 he proceeded M.D. and obtained the M.R.C.P., and in 1909 was elected a Fellow of the Royal College of Physicians of London. His earlier posts included those of house-surgeon, extern midwifery assistant, and demonstrator of anatomy at St. Bartholomew's Hospital, and house-physician to the Royal Free Hospital.

Llewellyn Phillips's career in Egypt began with the appointment of resident surgical officer to the Kasr-el-Aini Hospital, Cairo. He subsequently became physician to that institution, and was elected professor of medicine in the Royal School of Medicine at Cairo. During the war he held a temporary commission as lieutenant-colonel R.A.M.C., and commanded the British Red Cross Hospital at Giza; he was mentioned four times in dispatches. From 1914 to 1917 he held the appointment of physician to H.H. la Hussein Kamel, Sultan of Egypt, and for his services was made a member of the Orders of the Nile and of the Medjidieh. He had contributed articles on tropical medicine to various medical journals.

The following well known foreign medical men have recently died: Professor OTTO HEUBNER, for many years director of the children's clinic at the Charité Hospital, Berlin, and author of a textbook on children's diseases, aged 84; Professor KARL FRANZ, director of the women's clinic at the Charité Hospital, Berlin, aged 56; Dr. W. OETTINGER, formerly physician to the Paris hospitals; Dr. ANDRÉ COLLIN, aged 50, Paris, a writer on child psychology; Dr. ALEXBERT WINTHROP BRAYTON, aged 78, of Indianapolis, a prominent American dermatologist; Dr. GROSSICH of Fiume, aged 77, who introduced painting the skin with tincture of iodine before operations; Professor JEDLICKA, professor of surgical pathology and treatment at the Karl University at Prague, aged 56; Professor PREYSING, director of the ear, nose, and throat department at Halle University.

Medico-Legal.

MEDICAL WITNESSES' EXPENSES.

IN a motor collision case tried recently at Romford (Essex) County Court, it appeared that the cause of action arose at Uckfield (Sussex), and that the plaintiff, who lived at Eltham (Kent), had elected to bring his action in the county court within the jurisdiction of which the defendant lived. This had involved the calling by the plaintiff of medical witnesses—Dr. Cyril Williams, attached to the Uckfield Cottage Hospital, and Dr. John Higginton of Eltham.

Dr. Williams complained that the witness fee of one guinea which he had just received was entirely inadequate to cover the expense to which he had been put in journeying from Uckfield to Romford in order to give his evidence. To reach the county court at the proper time that morning he had been compelled to travel to London the previous night; further, he had had to engage another medical man to carry on his duties during his absence.

His Honour Judge Crawford said that Dr. Williams had been called from Sussex and Dr. Higginton from Kent, to the great inconvenience of both. There was no reason whatever why that case should not have been brought in a county court which would not have necessitated such long and unnecessary journeys. Such a payment as Dr. Williams had received was ridiculous. A medical witness was entitled to reasonable expenses for all the trouble and inconvenience to which he had been put. Judge Crawford added that he had no power to order it, but he hoped an adequate sum would be paid.

Universities and Colleges.

UNIVERSITY OF LONDON.

Lectures.

A COURSE of four lectures on current views on internal secretion will be given by Professor Swale Vincent at the Middlesex Hospital Medical School, Cleveland Street, W.1, on January 14th, 18th, 21st, and 25th, at 4 p.m. Dr. D. T. Harries will give a course of three lectures on the biological action of light at University College, Gower Street, W.C.1, on January 20th and 27th and February 3rd, at 5 p.m. Six lectures on cytology in relation to physiological processes will be delivered by Dr. R. J. Ludford at University College, Gower Street, W.C.1, on January 20th and 27th and February 3rd, 10th, 17th, and 24th, at 5.30 p.m. Admission to the lectures is free without ticket.

UNIVERSITY OF GLASGOW.

DR. J. M. MUNRO KERR, Professor of Obstetrics in the University of Glasgow, has been appointed Regius Professor of Midwifery, in succession to Professor Murdoch Cameron, whose resignation took effect as from December 31st, 1926.

SOCIETY OF APOTHECARIES OF LONDON.

THE following candidates have passed in the subjects indicated:

SURGERY.—F. W. Barton, G. Danby, J. H. Gillatt, T. W. Riseley, K. Roberts, N. S. J. Roberts (Section I), J. B. Scarr, S. Wray.
MEDICINE.—A. C. F. Barrow, G. Danby, H. J. Fordham, W. E. Ivers, C. H. Spencer.
FORENSIC MEDICINE.—L. Ashkenza, R. Bobo, G. Danby, S. K. Rigg, L. W. Rose, T. de L. Walker.
MIDWIFERY.—F. G. Hardaker, T. C. Lansdale, L. Wasef.

The diploma of the Society has been granted to Messrs. F. W. Barton, H. J. Fordham, W. E. Ivers, T. W. Riseley, J. B. Scarr, and C. H. Spencer.

Medical News.

A PAPER on the forecasting and control of cholera epidemics in India will be read before the Indian Section of the Royal Society of Arts by Sir Leonard Rogers, C.I.E., M.D., F.R.S., on Friday, January 28th, at 4.30 o'clock. The chair will be taken by Sir Michael F. O'Dwyer, G.C.I.E., formerly Lieutenant-Governor of the Punjab. Tickets for the meeting may be obtained from the Secretary, Indian Section, Royal Society of Arts, John Street, Adelphi, W.C.2.

DR. A. F. VOELCKER will deliver an Emeritus Lecture on "The unscarred abdomen," in the Large Lecture Theatre of the Middlesex Hospital Medical School on Friday, January 14th, at 3 p.m.

THE mid-sessional address before the Abernethian Society of St. Bartholomew's Hospital will be given by Professor W. Blair Bell on the evening of Thursday, January 20th; his subject is "Team work in research, with special reference to the nature and treatment of cancer."

DR. PERCY STOCKS, reader in medical statistics in the University of London, will give a course of lectures at University College, London, on vital statistics, on Fridays, at 5 p.m., beginning on January 14th.

THE next meeting of the Röntgen Society will be held on Tuesday next, January 11th, at 8.15 p.m., in the British Institute of Radiology, 32, Welbeck Street, W. A paper entitled "Some experiments on the production of rapid serial skiagrams from the screen image by means of a cinematograph camera" will be read by Dr. Russell J. Reynolds. At 8.30 p.m. a special general meeting will consider the proposed amalgamation with the British Institute of Radiology.

TWO courses of lectures have been arranged by the British Institute of Philosophical Studies during the Lent term, 1927. Mr. C. Delisle Burns will give a course of ten lectures on the philosophy of social life, on Tuesdays, at 6 p.m., commencing January 11th, at the University of London Club, 21, Gower Street, W.C. Professor J. S. Mackenzie will deliver ten lectures on the world of values, on Thursdays, at 5.30 p.m., commencing January 13th, at the Royal Anthropological Institute, 52, Upper Bedford Place, W.C. Particulars may be obtained from the Director of Studies, the British Institute, 88, Kingsway, W.C.2.

THE Fellowship of Medicine announces that the series of lectures on emergencies in medicine and surgery will be resumed on January 27th, when Dr. L. S. Burrell will lecture on haemoptysis, at 5 p.m., at 11, Chandos Street, W.1. The clinical demonstrations in surgery and ophthalmology will also be resumed during the month. From January 10th to 22nd there will be a course in medicine, surgery, and the specialties at the Prince of Wales's General Hospital and one in diseases of children at the Children's Clinic and the Royal Free Hospital. From January 11th to February 5th a series of lecture demonstrations will be held at the Bethlem Royal Hospital, and from January 17th to 29th a course in cardiology at the National Hospital for Diseases of the Heart. From January 31st to February 26th the London Lock Hospital will hold a comprehensive course in venereal diseases, and a special course in dermatology at St. John's Hospital will continue for four weeks from January 31st. Classes in pathology can also be arranged. From February 7th to 19th an all-day course in diseases of children will be held by the Paddington Green and the Victoria Hospitals. For one week, starting February 21st, a general practitioner's course will be given at the Royal Northern Hospital, for which no fee will be charged. Copies of all syllabuses and the programme of the general course of work can be obtained from the Secretary of the Fellowship, 1, Wimpole Street, W.1, who will also supply copies of the *Post-Graduate Medical Journal*.

AT the meeting of the Post-Graduate Hostel at the Imperial Hotel, Russell Square, W.C.1, on January 13th, at 9 p.m., Dr. E. I. Spriggs will discuss diverticulitis; on January 14th, at the same hour, Professor D. P. D. Wilkie will give an address on cholecystography. Dinner will be served at 8 p.m. (5s.). All medical practitioners are welcome.

AT a sessional meeting of the Royal Sanitary Institute, on Friday, January 28th, in the small Town Hall, Reading, a discussion on cancer will be opened from the point of view of the physician and the public authority by Sir Stewart Abram, senior physician, Royal Berkshire Hospital, and chairman of the Health Committee. Dr. T. Skene Keith, pathologist to the hospital, will consider "Cancer research to-day," and Mr. J. L. Joyce, F.R.C.S., senior surgeon, the present position of the treatment of cancer. The chair will be taken at 7.30 p.m. by Professor H. R. Kenwood, C.M.G., M.B.

THE fourth International Congress of Military Medicine and Pharmacy will be held at Warsaw at the end of May, when the following subjects will be discussed: (1) Evacuation in a war of movement, introduced by representatives of Poland and Brazil. (2) Etiology and prophylaxis of influenza, introduced by representatives of Poland and Denmark. (3) Sequels of traumatism of the skull, introduced by representatives of Poland and Greece. (4) Methods of chemical examination of arsenobenzols, introduced by representatives of Poland and Lithuania.

AT a meeting of the Pharmaceutical Society of Great Britain in the Lecture Theatre at 17, Bloomsbury Square, W.C., on Tuesday, January 11th, at 8 p.m., a paper entitled "Notes on preparations of the *British Pharmacopoeia*, 1914," by Mr. J. H. Franklin, will be followed by a discussion, and tea and coffee will be served in the Examination Hall at the close of the meeting. Medical friends and members will be welcomed.

THE next International Tuberculosis Congress will be held at Rome in 1928 under the presidency of Professor Raphael Paolucci, president of the International Federation against Tuberculosis.

THE next German Congress of Natural Science and Medicine will be held at Hamburg in 1928 under the presidency of Professor von Eiselsberg of Vienna. The number of members has increased from 2,500 to 6,000 in the last two years.

FOR the convenience of the medical profession, especially general practitioners, Dr. Camac Wilkinson has changed the hours at the Tuberculin Dispensary. In future the dispensary will be open at 32, Fitzroy Street, London, W.1, on Mondays and Thursdays from 2.30 to 5 p.m.

A NEW periodical, the *London Weekly*, made its appearance on January 1st, under the editorship of Dr. L. Haden Guest, M.P. In arrangement and scope it resembles closely some of the other sixpenny weekly reviews, and, as its subtitle—"Home and Overseas"—suggests, much attention is given to British politics and Imperial affairs, both in editorials and in contributed articles. The first issue includes a message from the Secretary of State for the Dominions, entitled "A Constructive Empire Policy," and a paper on research into the feeding value of pastures, by Dr. W. E. Elliot, M.P., Parliamentary Under Secretary of State for Scotland, and Dr. J. B. Orr.

THE Board of Trade has issued additional lists of articles chargeable with duty as from January 15th, 1927, under the Safeguarding of Industries Act, 1921. These lists refer to optical glass, elements, and instruments; laboratory porcelain; scientific instruments; and synthetic organic chemicals. Copies of the lists may be obtained from H.M. Stationery Office, price 2d. net.

THE American Psychological Association is commencing this month the publication of a monthly journal entitled *Psychological Abstracts*, under the editorship of Professor W. S. Hunter. The annual subscription, 6.25 dollars, is payable to Mr. H. S. Langfeld, Princeton University, New Jersey.

AN epidemic of leprosy has broken out in the Tartar Republic in Russia, and an epidemic of cholera in China, with a thousand cases a day.

THE West African medical staff list for October, 1926, may be obtained from the Crown Agents for the Colonies, 4, Millbank, S.W.1. Three lists of officers are given according to their grades, their grouping by colonies, and their qualifications and service.

THE Société de Chirurgie of Paris has received from Madame Lebaudy a gift of 50,000 francs for any orthopaedist of a neutral or allied country who invents the best prosthetic apparatus for the hand. Further information can be obtained from the Secretary of the society, 12 Rue de Seine, Paris.

THE Dr. Sofia A. Nordhoff-Jung Cancer Prize has been awarded for 1926 to Dr. Otto Warburg for his work on the metabolism of cultivated tissues, with reference to the biochemical aspect of the cancer problem.

SIX further pamphlets—Nos. 52 to 57—issued by the International Labour Office deal with formic acid, the incandescent mantles industry, lead poisoning, methyl alcohol, oxalic acid, and the painting industry. The information given about lead poisoning includes a comprehensive account of the sources of poisoning, the toxic action of lead, symptoms, diagnosis, prophylaxis, and treatment.

THE *Revista Médica Panamericana* is the organ of the Pan-American Medical Association, which has recently been founded to promote an exchange of scientific ideas and methods between members of the medical profession in North, Central, and South America. It is published in Spanish four times a year.

THE Victorian Branch of the Australian Association for Fighting Venereal Diseases has issued a memorandum on the problem of venereal diseases in which the incidence, prevention, and treatment are clearly explained for lay readers. Reference is made to the resolutions passed by the Council of the Victorian Branch of the British Medical Association in June, 1922, and the constitution and objectives of the Australian Association are detailed.

Letters, Notes, and Answers.

All communications in regard to editorial business should be addressed to ***The EDITOR, British Medical Journal, British Medical Association House, Tavistock Square, W.C.1.***

ORIGINAL ARTICLES and LETTERS forwarded for publication are understood to be offered to the BRITISH MEDICAL JOURNAL alone unless the contrary be stated. Correspondents who wish notice to be taken of their communications should authenticate them with their names, not necessarily for publication.

Authors desiring REPRINTS of their articles published in the BRITISH MEDICAL JOURNAL must communicate with the Financial Secretary and Business Manager, British Medical Association House, Tavistock Square, W.C.1, on receipt of proofs.

All communications with reference to ADVERTISEMENTS, as well as orders for copies of the JOURNAL, should be addressed to the Financial Secretary and Business Manager.

The ***TELEPHONE NUMBERS*** of the British Medical Association and the BRITISH MEDICAL JOURNAL are *MUSEUM 9861, 9862, 9863,* and *9864* (internal exchange, four lines).

The ***TELEGRAPHIC ADDRESSES*** are:

EDITOR of the BRITISH MEDICAL JOURNAL, *Aitiology Westcent, London.*

FINANCIAL SECRETARY AND BUSINESS MANAGER (Advertisements, etc.), *Articulate Westcent, London.*

MEDICAL SECRETARY, *Mediocera Westcent, London.*

The address of the Irish Office of the British Medical Association is 16, South Frederick Street, Dublin (telegrams: *Bacillus, Dublin*; telephone: 4737 Dublin), and of the Scottish Office, 6, Drumsheugh Gardens, Edinburgh (telegrams: *Associate, Edinburgh*; telephone: 4361 Central).

QUERIES AND ANSWERS.

TETANUS NEONATORUM.

"R. H. M." asks what is the maximum dose of tetanus antitoxin serum which can be given in a case of tetanus of the new-born, and would welcome any other information about drugs and their dosage in such a case.

INCOME TAX.

"C. T. C." began practice on March 13th, 1925—he "simply put up a plate and waited for patients." His earnings for the year to March 12th, 1926, were £30 5s. 4d., and for the following year, say, £180.

*** He is not liable to income tax until 1927-28, for which year he will be assessable at £180, less, of course, the usual reliefs. The assistance received from his friends does not affect his liability, nor does the payment by him of any sums to them, except that if he pays any interest to them he should deduct tax at the standard rate and show the facts on his income tax returns.

LETTERS, NOTES, ETC.

PREVENTION OF CORYZA.

DR. W. STUART-LOW (London) writes: It is well known that a great many people are constantly contracting colds in the head—indeed, are hardly ever free—but it is not so well known that there is a definite reason for this, that it is easily remediable, and that such people are a constant danger to others—their friends in the office and the home, and their fellow travellers in trains. The chief cause of this susceptibility to nasal catarrh is an anatomically disturbed nasal interior, mostly due to an injury sustained when young (even at birth), in the football field, while boxing, or accidentally, as from falls. This explains why one or two members of a family are constantly contracting colds and why the others escape, and why some members of an office staff are always falling victims while others are immune. An individual with a normal nasal interior, breathing even a not too pure atmosphere, is much less likely to become affected by nasal catarrh than another with a disturbed nasal interior breathing a purer air. To discover the cause of constantly recurring nasal catarrh it is therefore necessary that the nose should be skilfully examined, when some such disturbing factor as I have indicated will invariably be discovered. Until it is, and the cause eliminated, the person will go on contracting head colds, to his own great danger and the jeopardy of everyone coming into contact with him. The individual with the internal anatomy of his nose disturbed is so vulnerable to nasal congestions, and therefore head colds, that he is a veritable microbe generator and a bacterial disseminator in every coughing spasm and sneezing attack to which he is liable.

MIDWIFERY IN GENERAL PRACTICE.

"B.M.OXON." writes: The allegation that women of the poorer classes cannot be confined successfully and aseptically in their own homes seems to be based on two assumptions—first, that the home conditions are unsatisfactory and septic, and secondly, that the doctor is unsatisfactory and septic. The first assumption is, in the majority of cases, true, and helps to make the second true; but as the woman and her family have to carry on all their other physiological processes—that is, live—under these conditions, why devote public money to maternity homes and services which might more profitably be spent on improving the environment for all the physiological processes, of which parturition is but one? I mean that the money could be spent on better housing, with larger rooms and proper larders for food; the provision of clean bedding or periodical disinfection of existing bedding; proper sanitary accommodation in existing houses. In the second assumption there may also be some truth, but in the vast majority of cases I am sure that a doctor who is inefficient books few confinements, and that if a doctor is not completely aseptic in his technique it is due to force of circumstances which would not exist if the foregoing improvements in his patients' homes were carried out, and if there was provided a service of maternity nurses as adequate in numbers as the present district nurse is in efficiency. As a first step towards improving the aseptic technique the provision by public authorities of sterilized drums of dressings, gown, and gloves would seem to be an inexpensive and constructive criticism of things as they are.

THEORIES ABOUT CANCER.

DR. A. W. CRAWFORD (Bolton) writes to put on record his disagreement with the view that "all questions relating to the causation of cancer are dominated by the recent discovery of Gye and Barnard that the older theories have to a considerable extent lost colour." What they have discovered, he says, is the cell which is always attacked by cancer, and the only cell so attacked, namely, the epithelial cell, and they have caught it in the early stages of its progressive development, when it has reached the stage of visibility. He maintains that cancer is purely a degeneration of the nutritive cells and the blood, and that there is no vital activity in cancer cells. In his opinion the protozoal origin of cancer, like many other theories, will soon go by the board. Fourteen years ago he published the statement that embryonic cells which became cancerous were defective in their chromosomes and their glycogen.

POSTURE AS A FACTOR IN HEALTH AND DISEASE.

DR. M. O'BRIEN writes from Perth, West Australia, with reference to the paper by Dr. Forrester-Brown with this title published in the JOURNAL on April 17th, 1926. Dr. O'Brien begins by saying that the Class D individual shown in Fig. 2 (p. 691) is a type well known in medical practice, and owes most of his disabilities to weakness of the vertebral column, which is by no means always attributable to chronic ill health. Dr. Goldthwait, in his note on the paper, wrote: "The drooped relaxed figure is less good from every point of view than the erect alert figure." Dr. O'Brien thinks there can be no doubt that this is because the vertebral column, the support of the trunk, is weak; the trunk walls (ribs, intercostal and abdominal muscles) are relaxed, but this is probably secondary to the weak spine. The feeble spinal muscles of the upper dorsal region give insufficient support to the spine, which, [illegible]orward. The lower part of the dorsal spin[illegible] to compensate this, causing the increase [illegible]. The protuberant abdomen is partly produced by the lordosis and partly in some cases by visceroptosis, due to insufficient support being afforded to the viscera by the spine and trunk walls. Therapeutics,

therefore, become a matter of strengthening the vertebral column, and, though the treatment recommended by Dr. Forrester-Brown is undoubtedly valuable, very much better results would, Dr. O'Brien thinks, be obtained by encouraging spinal development. He recommends certain physical exercises for this purpose, some of which are already in use in various systems of physical training. The patient is directed to place and support himself for increasing periods of time on his heels and palms only, and, in another exercise, on his neck resting on a support, and on his heels, the legs and body being kept straight. If this second exercise is found impossible, the knees may be bent and the weight of the lower part of the body taken by the legs and soles of the feet. In another exercise the patient in the lateral posture supports his weight on one arm and the palm of his hand, and the side of the corresponding foot. In each exercise the body is held rigid, and no other part than those mentioned touches the ground. Dr. O'Brien adds that if these exercises are taken at least once daily they will cause in time a great increase in the strength of the spinal muscles, followed by that of the osseous structure, if the treatment is started at a sufficiently early age. With improvement in the strength of the vertebral column an increase in that of the trunk walls will result automatically in the great majority of cases. If it does not, a few simple running exercises will soon achieve this, producing a man who is well set up and who holds himself erect.

THE TOOTH-BRUSH.

"H. B. N." writes: The common tooth-brush enters the mouth and scours its crannies once or twice daily, and so may be a grievous source of infection. It may be worse than a contaminated food, for an infected brush used last thing at night may furnish septic germs, which will have a whole night of undisturbed warmth and moisture during which to become implanted. The use of the tooth-brush is growing. School medical inspection, and the generally improved conditions of the population at large, have made its use almost universal. But the methods, or rather lack of methods, of the sale of the article demand speedy amendment. One need only call on any chemist to discover how archaic and nasty is the present-day method of sale. The customer asks for a brush. He is handed a box or glass case with many patterns of brushes and allowed to take his choice. Brush after brush is examined, the thumb is rubbed along the bristles to determine the degree of stiffness and one is chosen. The rest go back into stock, both thumbed and unthumbed, until another buyer comes along. The purchaser thinks he has bought a new brush, but it may be in truth a second, or third, or *n*th hand brush, already contaminated by much handling. Tooth-brushes should be sold in a strictly hygienic manner, and this casual handling stopped. The buyer of a pencil does not expect to try the lead of his choice before buying: he looks at the mark BB, B, HB, H, or HH, and knows from the sign stamped on the wood of the pencil the texture he wants. Graduations of this sort might be applied more generally to tooth-brushes, and the practice of putting them up for sale in sealed transparent envelopes should be extended. At present only a few of the more expensive kinds are sold in this way. Even so, the buyer will be wise to disinfect a new brush before it is put into use by soaking it in a 5 per cent. solution of carbolic for six hours; then, after a wash in running water for a few minutes, it will be fit for use. In a recent note in the JOURNAL Dr. J. M. MacPhail (December 18th, 1926, p. 1206) questioned whether the dirty, flabby, damp tooth-brushes which he saw too often in the bathrooms and bedrooms of his patients were not more dangerous than no brush at all. There can be no doubt that too little care is given to this useful implement. It is used and dumped into its stand with scarce a thought, and used until the bristles come loose into the mouth and the thing is an annoyance. With a very little care the brush could be kept clean and sweet. Brushes should be chosen that have the tufts of bristles set well apart and not in a close pile; good spacing allows of easy drying. The secret of care is to wash the brush after each usage, strike it smartly (bristle downwards) on to a towel, so as to shake out the water, and then put it in an airy place to dry. Further, it should be given a weekly soak in carbolic solution. Better still would it be (as Mr. A. Annesley Gomes suggests in the JOURNAL of January 1st, p. 46) to have two tooth-brushes in concurrent use, each to be used for one week, turn about. The life of the brushes would be lengthened by this treatment, so cleanliness and economy go hand in hand. The traveller must needs use other methods. For him a long metal box, containing a supply of prepared chalk, should form his tooth-brush container. Into this the brush, after washing and drying on the towel, should be placed and kept between the times of usage, so that he may find a clean and dry brush awaiting him morning and evening, wherever he may be.

CARBON MONOXIDE POISONING ON A SHIP AT SEA.

A CORRESPONDENT sends an account of an oil tanker in ballast which arrived at a foreign port with the captain dead and the first and second engineers ill from carbon monoxide poisoning. He states that in cleaning out the holds in readiness to take a cargo of gasolene the pump had to be taken apart. The second engineer descended to the hold and fell on his back, face upwards. The first engineer heard of the accident, went down, and, as he set foot in the hold, fell similarly, face upwards. The captain, learning of the double casualty, without waiting to put on a gas mask, and being a powerful man, went down at once, but, before reaching the bottom of the ladder, fell under the pump, face downwards. The three men were brought up to the deck in less than ten minutes; the two engineers were bleeding from the nose and mouth. Artificial respiration restored the engineers after one and a half hours, but the captain appeared to have died instantaneously. The ship had previously carried a cargo of benzine, and our correspondent emphasizes the necessity of the Board of Trade insisting that anybody who enters a tanker's hold should be obliged to wear a gas mask. In this particular instance gas masks were available on the deck, though they were not used. He adds that this occurrence should also serve as a warning that care must be taken when "breaking the pump," which in this case was evidently a death trap.

RESEARCH IN PRIVATE PRACTICE.

IN the course of a letter on the possibilities and difficulties of research in private practice a correspondent relates his experience in endeavouring to ascertain which tuberculous patients were benefited by injections of human tuberculin and which by bovine. His criterion was the elimination of organic acid in the urine, and in the experimental work he was much assisted by a keen and trained dispenser, who had better facilities for continuing investigations than the inconvenient accommodation of a consulting-room or small dispensary in a private residence. The financial difficulty was also harassing. Our correspondent believes that more might be done in the way of research by private practitioners if textbooks were more explicit about the present limits of knowledge.

TATTOOING.

AT a meeting of the Royal Physical Society in Edinburgh a paper was read by Dr. Douglas Guthrie dealing with "The history and significance of tattooing and other forms of body-marking." The lecturer said that the decoration of the human body by designs was an ancient custom practised in Egypt and among the Inca and Maya civilizations. At the present day tattooing reached its highest level among the Japanese artists. In Europe generally the practice was largely confined to soldiers and sailors, although the designs, which were usually symbols of love, war, and religion, could rarely be regarded as artistic. Professional tattooists now used electrically driven needles, with all the precautions of modern surgical technique. Recently it had been seriously suggested that surgeons should sign their handiwork by tattoo marks on the skin, so that a subsequent operator might know what had already been done. The significance of tattooing among various races had been the subject of much investigation. Crude scars produced by burning or cutting were made by the Australian aborigines and were believed to confer immunity against disease. Scarring was also common in Central Africa to denote the tribe or secret society to which a native belonged. Among fair-skinned races true tattooing with pigments was naturally more effective. It is believed by peoples so far removed as the Eskimo and the Fijian that tattoo marks persisted upon the soul after death and served as a means of identification in the next world. The elaborate facial tattooing known as moko denoted the social position of the bearer among the Maoris. The design of this was of great artistic merit, and the custom of embalming tattooed heads had for a time rendered well tattooed Maoris unsafe, so that the export of heads had been prohibited by the New Zealand Government in 1830. The Rev. S. Nicholson, Scottish Secretary for the London Missionary Society, who had been twenty-five years in India, described the practice of tattooing in South India. Men were tattooed as a cure for rheumatic or other pains, and the Eurasian people were almost invariably tattooed to a considerable extent. Women were to a large extent tattooed, especially on the back of the hand, the calf, the middle of the forehead, cheeks, and chin, and the motive was said to be for a protection against the evil eye. The pigment used was lampblack mixed with milk or water.

WOMEN ON TEACHING HOSPITAL STAFFS.

MR. NORMAN M. DOTT, F.R.C.S.E. (surgeon, Royal Hospital for Sick Children, Edinburgh), writes: I observe that under the heading "Medical News" in your issue of December 25th, 1926, mention is made of the recent appointment of a woman to the full staff of a teaching hospital, and it is stated that this is believed to be the first occasion on which a woman has been made a member of the full staff of a teaching hospital in the British Isles, except in connexion with the Royal Free Hospital, London. In view of this statement it may be of interest to note that in May, 1925, Miss Gertrude Herzfeld was appointed to the full surgical staff of the Royal Edinburgh Hospital for Sick Children.

RENEWAL OF MOTOR LICENCES.

FOR the assistance of owners of private motor cars and motor cycles the Automobile Association is issuing a booklet entitled *Your Motor Tax at a Glance*, which shows the various amounts due for licences, either for the year or shorter periods. Information is also given regarding the allowances obtainable in respect of old cars, refunds for surrendered licences, and the necessary procedure for renewing licences. Motorists can obtain copies, free of charge, upon application by postcard to the Secretary, the Automobile Association, Fanum House, New Coventry Street, London, W.1.

VACANCIES.

NOTIFICATIONS of offices vacant in universities, medical colleges, and of vacant resident and other appointments at hospitals, will be found at pages 35, 36, 37, 40, and 41 of our advertisement columns, and advertisements as to partnerships, assistantships, and locumtenencies at pages 38 and 39.

A short summary of vacant posts notified in the advertisement columns appears in the *Supplement* at page 15.

An Address ON CHANGES IN THE CLINICAL ASPECTS OF DISEASE.*

BY

SIR HUMPHRY ROLLESTON, BART., K.C.B., M.D.,

REGIUS PROFESSOR OF PHYSIC IN THE UNIVERSITY OF CAMBRIDGE.

CHANGES in the clinical characters of disease are interesting not only to those of us who from the passage of time have watched once familiar maladies alter their features, and become rare, and have seen new ones come on the scene, but to everyone, because different years often show differences in the occurrence or the prominence of certain characters and manifestations of the common epidemic diseases. This is particularly true of what we all, however much we may deplore it in others, are driven sooner or later to call "influenza." In one year it is mainly naso-pharyngeal, in others pulmonary, gastro-intestinal, nervous, or, from the presence of a rash, may imitate scarlet fever, or, as in America in 1923, may be regarded as an epidemic of dengue (vide Hamer, 1923). On the other hand, it might be argued that what are called different types of influenza are in reality distinct diseases, as might be suggested by the separation of epidemic or lethargic encephalitis, which at its onset so often simulates influenza. During the war the virulence of influenza underwent a deplorable and dramatic increase in 1918, when there were two waves—the first in the spring with a comparatively low incidence of complications and deaths, and the other in the autumn, which was associated with *Streptococcus haemolyticus* infection and a high percentage of thoracic complications and mortality; this epidemic continued into 1919 and was world-wide. Thus within a short time there was a remarkable change in the character of a familiar disease, showing that this subject may be of immediate practical importance and not merely of historical interest.

Sydenham maintained that acute diseases showed (1) a long periodic evolution with a rise, decline, and fall extending over centuries; (2) seasonal variations with waves measured in months (as in the influenza of 1918) so that their character and reaction to treatment altered in a short time, a method successful in one epidemic becoming useless or even harmful in another; (3) that there was in his rather mysterious "epidemic constitutions" a special influence—telluric, as from the bowels of the earth, or climatic—which becomes dominant and by contaminating the atmosphere and acting on men's bodies disposes them to this or that disease, and impresses some definite character on the clinical manifestations of diseases prevalent at the time to the exclusion of other symptoms, the amplitude of this wave being measured in years. Major Greenwood explains the term "epidemic constitutions" as meaning that secondary infections, such as those familiar in influenza and measles, are just as important from the point of view of morbidity and mortality as the specific causes of disease. Sydenham, of course, had no knowledge of bacteriology, but Sir William Hamer, following in the footsteps of the English Hippocrates, has for years, with attractive eloquence and great ingenuity, argued the epidemiological relationship of diseases associated with different microbic agents—namely, that members of his "catarrhal group of diseases" (influenza, cerebro-spinal fever, acute poliomyelitis, and encephalitis epidemica) are variants of the same morbid process; at one time he ascribed them to the same virus acting under different conditions. Referring in 1924 to these and other acute diseases occurring in "the influenzal group of diseases," Hamer picturesquely wrote: "Surely we may recognize the protean influenza, now merely in mufti, but changing from one civilian garb to another under our eyes, and demonstrating unmistakably that the more it changes the more it is the same thing." In 1922 he argued that the hypothetical filter-passer determines the clinical manifestations which the *Bacillus influenzae* shall produce; and in 1925 he set out his thesis to the effect that in pandemic times the virulence of the influenzal germ was different from its activity in the intervals or trailing prevalences, giving rise in pandemics to a "shock attack" or influenza, and in the intervals apt to activate various secondary or associated micro-organisms—pneumococci, streptococci, meningococci. This is a much less iconoclastic view than that all the diseases in question are due to modifications of the same micro-organism, and narrows the gulf between the extremes of the epidemiological and bacteriological standpoints.

Recorded Changes in the Clinical Characters of Diseases.

There is now no need to insist that a change of type of disease does occur. A number of diseases are known to have changed their clinical characters; thus *scarlet fever* was very mild a century ago, fifty years ago it was extremely malignant, and now again it is a mild infection, although its prevalence cannot be shown to have diminished (Brownlee). Different types of the strains of the *Streptococcus haemolyticus* of scarlet fever have been described (Griffith), and it appears that these vary in different countries (James) so that clinical differences may thus be explained—for example, the extreme rarity of the disease in India. Though in addition to differences of virulence of the causal organism the resistance and antitoxin content of the individual must be taken into account, it would appear probable that simple mild scarlet fever may be due solely to pure streptococci, whereas the malignant forms are due to a secondary infection.

Acute rheumatism, which eventually may, like scarlet fever, be proved to be of streptococcal origin, has become less acutely arthritic, though not less frequent than it was thirty years ago; widespread and excessively painful and swollen joints and profuse sweating causing the miliary eruptions once so familiar are seldom seen now. The pulmonary complications described by P. M. Latham in 1846 have become very rare, and hyperpyrexia is almost unknown.

Out of Latham's 136 cases of acute rheumatism the heart was attacked in 90, or 66 per cent., and among these 90 cases the lungs were affected in 24, there being pneumonia in 18 (6 double), pleurisy in 2, and much bronchitis in 4. Among the 46 cases in which no cardiac lesion was detected there were pulmonary complications in 5 (pneumonia in 3). It may well be that some or all of these complicated cases were different from what would now be regarded as uncomplicated acute rheumatism, and that they were actually pyaemic or septicaemic in nature.

Possibly the practical disappearance of these thoracic complications is connected with the alteration in the treatment—venesection in the past, salicylates during the last forty-five years. Secondary infections may have been favoured by the prolonged course of the disease in the pre-salicylate days, of which a verbal record remains in the answer of "six weeks" made by an authority to the question "What is good for acute rheumatism?"

Articular and tophaceous *gout* is becoming a curiosity, but we comfort ourselves by reflecting on our wise temperance as compared with our many-bottled predecessors.

Pneumonia has altered its character to a considerable extent since the reappearance of influenza in 1889, broncho-pneumonic forms being now perhaps as frequent as the frank lobar form; but this is only to say that there are several forms of the disease. Among the cases due to infection with pneumococci alone the pneumococcus types I, II, III, and IV differ in virulence, and accordingly the mortality varies, being highest in cases due to type III.

In the past the character of *small-pox* has varied, so that occasionally epidemics have been extremely mild, as was noted by Sydenham, Jenner, and others (see Newman). There has of recent years been a noticeably mild form of small-pox, both in this country and abroad, which is thought to come from North America; so mild, indeed, is it that in Switzerland the public expostulated against vaccination as more disagreeable than the disease, and some regard it as distinct from small-pox and would give it another name—such as alastrim (a Brazilian word derived from the Portuguese *alastra*="something which burns like tinder, scatters, spreads from place to place" (Jorge)), amaas or kaffir-pox, para-variola, or para-small-pox. On the other hand, there are good grounds for the view that

* Presidential Address, Medical Society of London, January 10th, 1927.

it is a mild form of small-pox due to a virus with suppression of its toxic properties for man, although its affinities for other animal species have not been appreciably changed (Ledingham). It occurs almost solely in the unvaccinated, and protects against small-pox and vaccinia; experimentally the viruses of the three diseases have been shown to be variants of the same virus (Blaxall; Ledingham; Gordon). As a rule, though not invariably, the mild form breeds true, but the mild and severe forms of small-pox may occur side by side. The objection to employing a special name, such as alastrim, is that this may make it more difficult even than it is now to maintain the necessary preventive measures of vaccination and isolation.

Acute *appendicitis* has undoubtedly become very much commoner since 1889, when influenza broke upon this country after a respite so long (since 1848) that its nature was not recognized for some little time.

The word "appendicitis," which has been criticized as barbarous on account of its Latin basis with a Greek termination, was constructed in 1886 by Reginald Fitz of Boston, Mass.; before that time it was called perityphlitis. Kelly and Hurdon unearthed a case reported in France by Meslivier in 1759. If we hesitate to accept this explanation of Erasmus's illness in 1530 and the necropsy mentioned by W. Musgrave in 1684, which may have shown evidence of past appendicitis, the first case in this country was briefly reported in 1812 as "Disease of the appendix vermiformis" by "James Parkinson Surgeon Esqr." (obiit 1824), a general practitioner in Hoxton, who was also a palaeontologist, a writer of pamphle revolution, and the author of the famous Palsy" (1817) which has made his name disease," "Parkinsonism," and "the Parkinsonian mask." In 1836 John Burne, physician to the Westminster Hospital (1835-42), in a paper read to the Medical and Chirurgical Society, referred to twenty cases he had seen, including three examined after death at Guy's Hospital; and in the same year Thomas Hodgkin, pathologist at Guy's Hospital, gave an account of the condition, which Thomas Addison probably drew on in his often quoted description (1839).

It can hardly be maintained that the condition was overlooked entirely by a generation less acute than ourselves; indeed, had it been as frequent before its operative treatment came in as it is now, it is obvious that the mortality from acute peritonitis would have been very high. For the increased occurrence of appendicitis various factors have been suggested, such as alteration in diet, greater consumption of meat—fresh, frozen, or tinned—fresh fruit, and antimony from the red rubber of bottle-stoppers. The association with the return of influenza, which has an intestinal form, is certainly significant.

A well established change in chronic disease within the lifetime of some of us is the great diminution of *chlorosis*, which may be contrasted with the, to my mind, increased incidence of pernicious (Addisonian) anaemia. The declension of chlorosis has been ascribed to several causes, such as better feeding, especially more meat, and to the change of fashion as regards tight lacing (F. P. Weber), the etiology of the disease being, according to Rosenbach and others, succinctly expressed as the corset. This explanation of the present rarity of the green-sickness of young women has not escaped adverse criticism (Elder; Waterhouse).

It is generally, though not unanimously, believed that *urinary calculus* in the Eastern Counties has undergone a well marked diminution; it must be remembered that fifty years ago operations for stone were among those most often undertaken, and therefore bulked more prominently than at the present day. The statistics collected by R. Smith and Yelloly make it clear that a hundred years ago urinary calculus was much commoner in Norfolk than in other parts of England and Wales.

R. Smith, making considerable allowances so as to avoid minimizing the incidence of calculous disease, estimated that in 1819 there were not more than 200 cases annually in the whole of the British Empire, and that there were as many cases in the Norfolk and Norwich Hospital as in either Scotland or Ireland. Yelloly found that from 1772 to 1827 inclusive there were 649 lithotomies in the Norfolk and Norwich Hospital, or one in forty admissions, and on an average 11½ a year; that stone occurred in one out of every 34,000 persons in Norfolk as compared with one out of 108,000 persons in the rest of England and Wales, with a population of nearly twelve millions; and that it was less rare in Norwich, London, and other towns than in the surrounding country districts.

The reason for this relatively high incidence of urinary calculi in Norfolk is obscure. Dr. John Yelloly, who was physician to the London Hospital from 1807 to 1818, in 1805, when the Medical and Chirurgical Society formed in opposition to the Medical Society of Lon then under the blight of Dr. James Sims's long preside was with Dr. A. J. G. Marcet one of the founders first secretaries of the new society, of which he was l treasurer, was also physician to the Norfolk and Nor Hospital from 1820 to 1832, and in 1829 and 1830 wrot the tendency to calculous diseases. He very tentati put forward the view that the "large employment o fermented farinaceous food" was, by the resulting indi tion, *a*, if not *the*, cause of the prevalence of ston Norfolk.

Syphilis, when it breaks out in a previously uninfe race, is much more virulent than in civilized and syphil countries; but the much milder type of the cutaneous bony lesions of syphilis in this country can hardly ascribed solely to some approach to relative immunity the influence of more general early recognition and effic treatment must be taken into account.

The diminution of malaria, yellow fever, plague, enteric fever, and the practical disappearance of hy phobia and scurvy in this country, have been determ by administrative and hygienic measures. It has suggested that the milder small-pox at the present tin due to the better hygienic conditions, thus correspon with the lower fatality of typhus and relapsing f when these rare diseases occur in this country, and t increased mortality in conditions of famine, as in Sc during the war. No doubt this factor is important, it is not the whole story, for in the past small-pox scarlet fever have had their mild interludes. Past explanation, which takes into account both a change in virulence of the infective agents and altered conditio environment, seems nearer the mark, but there ma some further and obscure factor to account for these i spaced variations in virulence.

Hydatid disease has become much rarer in England commoner in the Argentine Republic, but this is de dent on variations in the source of infection—namely, dogs attendant on cattle. Forty years ago hydatids by no means rare around Cambridge, now the disea most exceptional; possibly, like the extinction of malari the fens, this is connected with the draining and reclai of the land. Conversely, the influence of certain in tries in producing disease, such as silicosis, carcin (sweeps', paraffin workers', mule-spinners'), ana (benzol), and jaundice (trinitrotoluene and te chlorethane during the war), have attracted more, more skilled, attention. It is rather remarkable chimney-sweeps' cancer and mule-spinners' cancer practically confined to this country. On the other h the effect of prophylactic measures is well shown in great diminution of lead poisoning during this century

Effect of Treatment.

It may be interesting to mention incidentally an artif factor which had modified disease as many of us see namely, the influence of early and efficient treatment. modification of syphilis so that the terrible tertiary les of bone are now seldom seen may be in part due to t thorough treatment. Enteric fever has become rare, diphtheria has lost much of its terrors, thanks to phylactic and curative measures. The influence of Jenne vaccination is too obvious to labour, but attention ma drawn to an incident in connexion with inoculatio the eighteenth century: an uneducated Shetlander, Williamson, practised inoculation with small-pox cr which he dried and kept for years before using; with attenuated virus he never failed to obtain protection never had any bad results.

Surgery, too, had not been idle; thus early laparot for perforated or leaking gastric ulcer has made subphr gas-containing abscesses extremely rare. As the resul improved methods of diagnosis, and so earlier operat on cholecystitis, the character of gall-stone cases has un gone some change, and in Paris at any rate cases of st in the common bile duct have become rare (Petit-Dut and Mestrezat).

Disease: A Reaction, not a Morbid Entity.

It would indeed be strange if diseases always remained the same, for a disease, as the late Sir Clifford Allbutt insisted, is not a fixed morbid entity, such as might perhaps be visualized by the entry of an evil spirit into a man, but the reaction of that complex organism the body to some infection or injurious influence. There have been many definitions of disease, but Adami's (1910) gives a good impression of the potential variability in the reaction we call disease, and runs as follows: "Disease is a process or succession of disturbances induced by any agent which disturbs the normal activities of the organism as a whole or of its constituent parts." It is clear that the character of the reaction must depend on the condition of the individual host and on that of the cause—of the soil and the seed. Both of these may vary; for example, the difference in the manifestations of infections at the various periods of life shows how the state of the soil modifies its reaction. Variations in the virulence and doses of pathogenic organisms, supposing that the resistance of the host remains the same, would lead to changes in the reactions. With variations in the conditions of both the soil (the host) and the seed (bacteria and other environmental influences) it is clear that the clinical reactions and manifestations must alter in a corresponding degree. A highly virulent strain of micro-organism falling on a group of men whose resistance is either inherently weak or has been lowered by adverse influences should lead to an epidemic with fulminating attacks; whereas an attenuated infection acting on persons with fair powers of resistance would cause mild attacks, or fail to produce any recognizable result except to confer immunity. Further, a greatly lowered general resistance might allow micro-organisms ordinarily harmless to become pathogenic.

Experimental Epidemiology.

The experimental methods applied to epidemiology by Topley (assisted in the statistical aspects by Major Greenwood) in this country, and by Flexner, Webster, and other workers at the Rockefeller Institute, New York, who produced epidemics in laboratory animals, are throwing much light on the problems of spontaneous epidemics in man—such as the virulence of micro-organisms, the factor of the doses of micro-organisms, the susceptibility of the host, and, what is apparently a different problem, that of the herd. The variations in these factors give rise to permutations and combinations in the causation of epidemics, and further, "it is probable that additional factors not connected with the dosage of the parasite, nor with variations in the biological characters of the parasite or hosts, play a part in the spread of an epidemic" (Topley); and, though secondary infections, the part played by bacteriophages and by diet may possibly affect the relations between the parasite and the host, little is known about the additional factors. These problems of epidemics obviously bear on those of a change of type of disease, but at present they await a final solution.

Changes in the State of the Soil (the Host) as Responsible for Alterations in the Clinical Manifestations.

That continued exposure may be followed by a greater or less degree of immunity, as the result of unrecognized vaccination, in exposed persons is suggested by several observations: the increased resistance of laboratory animals who have survived an epidemic; the growing immunity in schools and institutions to diphtheria and to scarlet fever, as shown by the Schick and Dick tests; the acquired immunity to malaria and yellow fever shown by natives (who may also have had the disease); and in an indirect manner by the severity of epidemics of measles among the inhabitants of isolated countries where the disease rarely occurs—for example, the Faroe Islands (1781 and 1846), Fiji (1875 and 1907) and the neighbouring island of Rotuma (1911), and the Shetlands; the ravages of the common cold when introduced into St. Kilda; and the rapid and fatal course of tuberculosis in persons coming from regions where the disease is unknown. On the other hand, the long persistence of epidemic diseases, especially measles, shows that any racial immunity that can be thus produced is very slow. Webster, however, has brought forward experimental evidence of its occurrence, and on clinical grounds there is some reason to believe that a gradual racial immunity may be developed in the course of years.

Changes in the constitution or make-up of the members of a race must exert some influence on the liability to special diseases, and as the structural architecture of a nation becomes modified by admixture with other races, some alteration in the prevalent chronic disorders would be anticipated. The Jews are particularly prone to some common pathological states, such as diabetes mellitus, obesity, and arterio-sclerosis, and some rare conditions occur chiefly among them, such as amaurotic family idiocy, obliterating thrombo-angiitis, pentosuria, lipodystrophia, and the recently described Niemann's disease (Bloom) which had previously been included in Gaucher's splenomegaly. Draper, who holds that the association of certain diseases with special anthropometric types is as distinct as the anthropometric racial types, speaks of the incidence of the above diseases in the Hebrew race as evidence of "a pathological tendency of physiological nature."

Environment, hygienic conditions, alcoholism, food supplies, and so forth, influence the general resistance and so the susceptibility to disease. It would be interesting to know which of the two factors, the variations in the host's resistance and the pathogenic power and the dosage of the microbe, is more important in the production of infection. According to Webster the mortality of an epidemic depends less on fluctuations in microbic virulence than on variations in the susceptibilities of the hosts; but Topley's critical conclusion is to the effect that in laboratory epidemics the existence of innate differences in the resistance of the hosts is non-proven. In human disease, however, it would seem reasonable to anticipate that impaired resistance would play a more dominant part in favouring infection than microbic fluctuations.

From investigation of the streptococci constantly present in dental root infections Knott and Spencer-Payne conclude that the production of systemic and metastatic infections depends more on diminished local resistance than on the specificity and selectivity of the streptococcal strains.

The increased frequency of subacute and chronic bacterial endocarditis, and of pernicious anaemia if this be accepted, raises the question whether or not this can be correlated with correspondingly great incidence of focal infections, such as dental, tonsillar, or intestinal, which in their turn are due to a widespread diminution in resistance allowing micro-organisms, such as strains of streptococci, usually saprophytic to become pathogenic (Horder; Dawson). The definite increase of subacute and chronic bacterial endocarditis, especially in ex-service men, since the war, with its infecting and depressing conditions, is an argument in favour of the view that a diminished resistance is the probable responsible factor. War has always altered the bills of mortality more by spreading epidemic diseases, such as dysentery, enteric, typhus, cholera, and malaria, than by wounds, though in the great war there were exceptions to this rule on the Western and other fronts. Malaria, which had become extinct in Flanders, reappeared after the advent of infected Portuguese troops and flooding of the country to arrest the German advance, thus recalling the disastrous Walcheren expedition of 1809; the extremely resistant character of malaria to quinine treatment during the war in the Macedonian area is another noteworthy incident.

The adverse circumstances of war, entailing deficiency of food, destitution, overcrowding, and insanitation, may so reduce the resistance of those concerned that diseases not usually prevalent or sometimes previously unrecognized come into prominence. This, as Dr. Horsley Gantt has shown, was particularly the case in Russia, where rickets, famine or hunger oedema, famine cachexia (without oedema), acute enteritis and peptic ulcer, and typhus and relapsing fever (immediately due to animal vectors) became rampant. War oedema occurred during the Napoleonic campaigns and the siege of Paris, and, it is said, in the concentration camps during the Boer war, under the name of epidemic oedema (Maliwa); it has been seen apart from war. Scurvy on land has been a feature of wars since the Middle Ages, and out of 143 epidemics analysed by Hirsch 55 were during hostilities. In Russia recently scurvy was the least frequent of the deficiency diseases, probably because the very great food scarcity led to the consumption of bark

and leaves (Gantt), but it was prominent in some other theatres of the great war, especially in Mesopotamia, where 11,445 cases occurred in the second half of 1916. Tuberculosis increased in all the combatant European nations. In Germany and Austria rickets became extremely common, and keratomalacia and blindness appeared; in Germany there was an increase of jaundice and acute yellow atrophy, quite apart from the factor of syphilis and its treatment by salvarsan preparations. Epidemic encephalitis, which was practically a new disease described by Economo in Vienna in 1917, soon, like influenza, spread over the world, and is still with us. The environmental conditions of stationary warfare created trench fever and trench nephritis, the latter having been seen seventy years before in the War of the Rebellion in North America, and made spirochaetosis icterohaemorrhagica common instead of a curiosity. But from their etiology these conditions were more of the same nature as the epidemic infections—enteric, dysentery, cholera, malaria, and in Russia syphilis—which are an outcome of circumstances favouring mass infection, and they were not, in the main, the outcome of changes in the resistance of the troops.

Enforced moderation in diet was naturally followed by a diminution in disease due to excess (in a sense the reverse of deficiency diseases); thus in Russia Gantt reported a fall in chronic alcoholism, adiposity, appendicitis, and diabetes; the incidence of cholecystitis and gall stones gradually fell from 4.7 per cent. of all out-patients in 1914 to 4 per cent. in 1917, and then dropped suddenly to 1 per cent. in 1918 and 0.8 per cent. in 1919, thus suggesting the importance of overeating as a causal factor. In Germany the war showed a diminution in diabetes, in acute pancreatitis (Wilms), and in arterio-sclerosis, but the last became more frequent in Russia.

It is tempting to associate with the popular cry of "the wear and tear of modern life," and the nervous strain entailed by the more rapid fashion of existence, an increase of functional and organic nervous diseases, of diabetes, high blood pressure, and arterio-sclerosis. Thus in the United States of America, where intensity and "hustle" are characteristic features of life, the death rate of cardio-renal disease far exceeds that due to any other cause, and was responsible for the deaths of the last two Presidents (F. M. Allen). On the other hand, the frequency of functional nervous disease is no new phenomenon, for George Cheyne, in *The English Malady* (1733), estimated that one-third of the upper classes were thus afflicted, and Thomas Trotter, in his *View of the Nervous Temperament* (1807), went one better by putting the incidence at two-thirds of all civilized communities, poor as well as rich. It is difficult, therefore, to be certain, probable as it may appear, that neurasthenia and functional disease are so much commoner now than in the past, for statistics, as apart from impressions, such as those of Cheyne and Trotter, are hardly available, and in the comparatively short period covered by a medical generation or two it is far from easy to estimate accurately the degree of change that occurs. Although telephones, motors, and aeroplanes increase the rate of living, they also have compensating advantages, and wars and alarms were more constant in the past. It is impossible to be certain that there has been an increase of high blood pressure on account of the recent introduction of the sphygmomanometer and the absence of any statistics in the past on this point. The indirect evidence that might be sought from arterio-sclerosis is rendered doubtful by want of exact correspondence between the two, high pressure being only one, and not the sole, cause of arterial change; but arterio-sclerosis was common in ancient Egypt. The greatly increased expectation of life, which is a noticeable result of public health activities, has altered the forms of disease responsible for the bills of mortality; malignant disease, arterio-sclerosis, and chronic cardio-renal disease have become more prominent, whereas tuberculosis has declined.

Changes in Bacteria as Responsible for Alterations in Clinical Manifestations.

Variation and mutation are more readily and rapidly produced in bacteria than in higher animals and man, and serological research has shown the perplexing differe that may thus occur, for example, in the salmonella g (Andrewes, P. Bruce White).. Different strains which morphologically and culturally identical vary in their logical reactions in a remarkable manner; thus *Bac paratyphosus* B and *Bacillus aertrycke*, which are i tinguishable morphologically and culturally, are logically different and also distinct in their clinical eff the first causing paratyphoid fever, the second acute *poisoning*. Differences in virulence may, as Pas showed long ago by growing anthrax bacilli at 40° C. producing a relatively non-virulent strain, be modifie environment, nature of nutrient material, temperat and possibly other factors.

As a rule, however, the influence of culture media and c laboratory methods is in the direction of diminishing, no increasing, virulence; there are exceptional instances of incre pathogenicity induced by culture—for example, of the pne coccus (Felton and Dougherty) and of the meningococcus (E. G Murray); and Flexner and Amoss observed revival of the p myelitis virus after being in glycerol for several years. Accor to Webster, virulent strains come into being by some means subtle than animal passage.

Associated with the known different types of the typh paratyphoid group, dysentery bacilli (Shiga and Flexn and to some extent of the pneumococci, there are correl differences in the clinical manifestations; in cerebro-sp fever the different types of meningococci have been conne with different clinical reactions; thus, according to Dop the predominant infective meningococcus before the E pean war was Type A (Gordon's Types I and III), whe later it became Type B (Gordon's Types II and IV); Ne correlated the greater frequency of cases of septicae and of lesions, such as rashes, arthritis, and irido-cycl with this change to Type B. Thus changes in the clin aspects, for example, of enteric fever and cerebro-sp fever, may be due to infection with different types of typhoid-paratyphoid group and of the meningococcus. is reasonable to believe that further evolution of s varieties might be accompanied by such alterations in clinical picture as to constitute new diseases, as indeed occurred in the differentiation of typhoid and paratypl fevers. The adaptability of bacteria to altered conditi so that a harmless saprophyte living on the surface of body can be changed, in the laboratory or outside, int pathogenic micro-organism which invades the body gives rise to disease was emphasized by the late J. Adami (1918), who instanced as a probable example transformation of some previously harmless diphther bacillus into the virulent diphtheria bacillus to account the appearance at the beginning of the last century diphtheria, a disease so sharply cut that it could hav have been overlooked by all physicians until Bretonn of Tours gave his classical description in 1821. Am animals hog cholera, unknown before the sixties, wher appeared in the United States, is another example support of the view that bacteria can and do unde evolution from a saprophytic to a pathogenic state. has been mentioned above, the occurrence of second infections is a factor of importance in altering the clin manifestations of an infective disease.

The two variations—in the soil and in the seed—thou mentioned separately, must often be combined in vary degrees, and must play an all-important part in the chan in the clinical aspects of disease.

GLEANINGS FROM THE STORY OF THE THYROID GLAND.

An Address delivered to the South-West Wales Division of the British Medical Association

BY

SIR JOHN LYNN-THOMAS, K.B.E., C.B., F.R.C.S.,

CONSULTING SURGEON TO THE CARDIFF ROYAL INFIRMARY AND SURGEON TO THE CARDIGAN HOSPITAL; CHAIRMAN OF THE DIVISION.

THE accounts of the physiology of the thyroid gland and the surgery of goitre given in the textbooks of my early student days took less than three hours to read and study; it is, however, necessary to point out that this apparent cramming course was not so intensive as it sounds. In the index to the fourth edition (1883) of the standard *Textbook of Physiology* by Michael Foster there is no reference to the thyroid gland. Incidentally, it was in this year that attention was drawn in Switzerland to post-operative myxoedema, as will appear later from the very interesting note sent by my friend Dr. Albert Kocher in reply to a request to let me have an epitome of the work his father, the late Professor Theodor Kocher, had done as regards the subject-matter of my address to you. I am glad to recall that both Professor Theodor and Dr. Albert Kocher visited the area of our South-West Wales Division many years ago and saw examples of our thyroid troubles, to my edification.

On the question of the surgery of goitre I have to confess that for a few years after qualifying I deprecated operations except in emergency—in fact until I visited the great master and pioneer at work in Berne. This attitude, I may add, was due almost entirely to the teaching and practice at my school, for I, being imitative, had operated on a Gasserian ganglion and did an experimental decompression on acromegaly years before I felt justified in doing a thyroidectomy. My view was nurtured in my nonage by reading the seven pages devoted to diseases of the thyroid gland in the standard work *A System of Surgery* (Holmes, vol. 3, 1883), and was fortified years later by witnessing a brilliant surgeon attack a bronchocele and wallow in an operation masked with blood and many sponges, and constantly harassed by a Clover's bag—one special sponge was conspicuously held over the field to deliver fluid if necessary; later he descanted on its value should a gurgling sound be heard indicative of air being drawn into one of the veins! He also pooh-poohed the adoption of an innovation which he flippantly described as a "cut-throat" incision.

When I witnessed the first Kocher operation performed by its originator with deliberation and care, without unnecessary spilling of blood, with unsurpassed surgical cleanliness, with non-variable speed, neither slow nor quick, but a safe "Kocher speed," I instantly became a convert. I was astonished and impressed with the novelty and value of the Kocher screen which completely safeguarded the field of operation from infection from the patient's mouth, from the anaesthetist, and from interested onlookers; the patient's hands also were secured from doing harm.

We re-read to-day, with gratitude to Professor Theodor Kocher, the nightmare which appeared under "treatment" in the *System of Surgery*, and obsessed so many like myself, knowing that it is now gone for ever; there we read such statements as that "fibrous bronchoceles are best treated by setons"; that "the best treatment for cystic bronchoceles is . . . tapping the cyst with a trocar and cannula, emptying it, injecting a solution of perchloride of iron (two drachms to an ounce of water) . . . to be repeated if necessary until suppuration is established"; and that "removal of a bronchocele is usually a grave operation . . . the danger of haemorrhage is considerable." Nevertheless, the volume contains shrewd clinical observations, and exhibits discernment and the true scientific outlook in not accepting as truth that which is not proven. For example, it is said:

> "The endemic form of bronchocele, or goitre, occurs chiefly in association with cretinism and seems to have some hitherto unexplained connexion with geographical conditions . . . the cause commonly assigned—namely, the use of melted snow, or of water impregnated with calcareous or earthy particles—is unsatisfactory. . . . Although the Korrawurrees can get nothing but snow for some months in the year, they are not so subject to goitre as those who live at the foot of hills where there can never be any snow water."

The importance of this quotation will be seen when I come to discuss Professor Kocher's views as to the causation of goitre. From that time to the present the literature on thyroid gland and goitre has grown so voluminous that I can only attempt to bring to your notice a few gleanings, after reading to you the most valuable and interesting *aperçu* by Dr. Albert Kocher of his father's work on the subjects.

NOTES ON THEODOR KOCHER'S WORK ON THE THYROID GLAND.

BY

DR. ALBERT KOCHER.

From 1866 to 1872 Theodor Kocher was assistant of Professor Lucke in Berne. During that time Lucke performed ten goitre operations; of the patients nine died. Two years after having been elected Lucke's successor in the chair of surgery at the University Theodor Kocher, in 1874, published his first paper on the thyroid gland—on the pathology and treatment of goitre. In this paper he published his first thirteen goitre operations, with two deaths only. In this paper he said that there were three forms of operation for goitre: total thyroidectomy, partial thyroidectomy, and enucleation. He said that the total thyroidectomy was an easier procedure "than partial thyroidectomy, but it is a question whether there is any connexion between the total extirpation of the thyroid gland and the altered mental condition I have noticed in one of my cases of total thyroidectomy." His goitre operations were already at that time done on a preconceived plan—he sought in each case to ligate the arteries first. A few years later (1887) he published his first operations for malignant goitre, describing a method of "*évidement*" of soft malignant tumours, especially intrathoracic ones.

In 1883 he published the results of his first 101 goitre operations. He gave at the same time a list of all the goitre operations done down to 1883. He found that with his own 101 cases 240 goitre operations had been performed. In this same paper he detailed his exact method of operating, and then described the consequence of total thyroidectomy. He had reviewed all the cases he had operated on, and in the eighteen cases where total thyroidectomy had been done he found the typical picture of myxoedema. In April, 1883, he read a paper on the consequence of total thyroidectomy at the German Surgical Congress, calling the disease "cachexia thyreopriva."

From that moment he began to treat these cases of total thyroidectomy by making transplantation of pieces of thyroid gland or goitre in many different parts of the human body —skin, muscle, arteries, peritoneum, intestine, etc.—but the effect was only temporary. Later on he reviewed these cases as often as possible; he found that those in which a real total thyroidectomy had been performed died within seven years after the operation (*no thyroid tissue could be found at the post-mortem* examination), whilst those who lived longer had developed a new but small goitre, proving that total thyroidectomy had not been done.

In the years from 1880 to 1890 he studied the question of the etiology of goitre, examining thousands of school children all over the canton of Berne, and examining especially the water at the different places. In 1889 he published a map showing a close connexion between geological formation and the distribution of goitre. At that time, in a public lecture, he urged the Government to have the drinking water in the public schools boiled, or to add iodine to it, in order to prevent goitre. In 1889 he published the results of another 250 goitre operations. In this paper he described his exact procedure in the operation he named "enucleation resection," including the collar incision of the skin. This method of operation for goitre was that used by him in all his goitre operations without any modification; it became and remains to-day the classical method of operation all over the world for nodular goitres. In fact, nothing new has been added to this method of operation anywhere or by anyone in the following thirty-seven years—that is to say, until the present time. This method not only included the collar incision of the skin now universally used, but also gave the exact method of leaving all healthy thyroid tissue behind, and so to assure a sufficient function of the thyroid, to prevent myxoedema, to avoid any lesion of the recurrent nerve and of the parathyroid glands, which became known only later on. Even nowadays, when the bilateral operation of nodular goitre is recommended by many surgeons, Kocher's enucleation resection is done on both sides. Hotz calls it the bilateral Kocher operation.

In 1892 Theodor Kocher published his paper on the origin and prevention of cretinism, in which he described a case of congenital goitre with cretinism, and showed that cretinism was due to lack of thyroid function, and could be prevented by the same measures as those by which goitre can be prevented. This point of view was very much, and for a long time, opposed, but has nowadays become the general opinion.

In 1887, when showing a case of Graves's disease to his students to illustrate a clinical lecture, he demonstrated the hypervascularization of the thyroid gland, and suggested that the symptoms of the disease were due to hyperthyroidism. He was the first to perform a successful operation for goitre in a typical case of Graves's disease. In 1897 he published sixty-nine cases of Graves's disease operated upon, with only four deaths.

In 1895 he read a paper on the action of iodine on goitres. In that paper he suggested that the normal thyroid gland must contain iodine, as the action of desiccated thyroid gland on goitres was the same as that of iodine. Unfortunately, the professor of chemistry at the University of Berne who made the investigation could not find any iodine in the thyroid glands he examined. A year later Baumann in Freiburg published his article on the normal iodine content of the thyroid gland.

In 1895 Theodor Kocher had done 1,000 goitre operations; in 1901, 2,000; and in 1905, 3,000. At the time of his death in 1917 he had personally performed 6,000 goitre operations.

In 1907 he read the opening paper at the German Congress of Internists at Munich, on the pathology of the thyroid gland, and in 1906 gave the annual oration (on the same subject) before the Medical Society of London (BRITISH MEDICAL JOURNAL, 1906, vol. i, p. 1261). This work was the starting-point of modern endocrinology, and contained all what we know at present of the pathology of the thyroid gland. In fact, nothing important has been added to it since. In 1907 he published also an important paper on malignant goitre, describing the different forms in conjunction with Langhans.

In 1908 he described his methods of gland grafting, publishing seventy-nine cases of transplantation in myxoedema, mongolism, and hypothyroidism. He specially recommended to take the transplant from a gland of a case of exophthalmic goitre, thus proving by his successful cases that the gland in Graves's disease is hyperactive and not toxic. In the same year he published the exact analysis of the blood in 260 cases of Graves's disease, showing that the leucocyte formula displayed a typical change, and a few years later he also showed a typical blood change in myxoedema, pointing out that the number of the lymphocytes in the blood was connected with the functional change of the thyroid gland. This close connexion of the lymphocytes and lymphoid tissue to the secretion of the thyroid gland has been established histologically lately by Williamson.

In 1910 Theodor Kocher gave the classical pictur *Iodbasedow*, showing that the use of iodine can pro Graves's disease in certain forms of goitre, and dra attention to the harm that can in consequence be done b use of iodine in goitres. Though at present the Mayo s has shown that Lugol's solution can in certain cases of Gra disease bring about an improvement and make the oper less dangerous, Kocher's observations and statements re quite true. The exact role of iodine in the disease is, how far from being explained.

In 1911 Theodor Kocher published the results of 1,200 o tions on the thyroid gland in Graves's disease, with 80 per complete cures. In that paper he showed how the disease be diagnosed in an early stage, and advocated early opera He described a new lid symptom which appears very ea namely, the contraction of the levator palpabrae super when the patient is made to look up and down quickly.

In 1909 he was awarded the Nobel prize for his rese work, and especially for his discovery of the function of thyroid gland. He then gave before the Academy of Med of Stockholm an address in which he drew a classical pi of the minor functional troubles of the thyroid gland—hypo-hyper-thyroidism. These conditions have been described a since without any reference to Theodor Kocher's publica In the same year he described a functional test for diag of thyroid disease, which consists of an exact blood exan tion, specification of the leucocytes, and determination of time of coagulation; thyroid substance is then administere the patient, and the blood count and coagulation test repeated, and change in a typical way, according to the fun of the gland. The diagnosis of the minor functional trou however, as well as the functional method of diagnosis, not become generally known or used, as being methods difficult for the ordinary practitioner. Albert Kocher has this method ever since, and uses it also for all the endoc glands, with similar results. To this method is due successes in endocrinologic treatment; he finds it much exact and sure than the control of basal metabolism.

At the meeting of the Swiss Surgical Congress in 1917, a months before his sudden death, Theodor Kocher reviewed his goitre operations, from which it appeared that he had at that time a mortality of 2 per mille in operations of ordi goitre and of 2 per cent. in Graves's disease. At the s time he gave a summary of our knowledge of the etiolog goitre, recommending the prophylactic treatment.

It is worth while to recall all that has been done for advance of our knowledge about the thyroid gland by The Kocher, and, under his guidance, by his people. It is n worthy that Theodor Kocher never made any fantastic st ments, but only drew those conclusions he could really pr giving entire credit to all that others have contributed to question. Since his death very little sound work has done on the subject, but very many theories have been advan It is sad to note that the credit Theodor Kocher deserves is given to him by many authors of the present day.

I feel sure you wish me, as your chairman, to thank Albert Kocher for an historical contribution which car the knowledge of his father's work beyond any records I h seen in the English language. Personally I share the fi sentiments expressed in the last paragraph: I know it be true also in other branches of surgery; still, I am g to be able to say that things are slowly mending. In review of Crile's book on the *Thyroid Gland* (BRIT MEDICAL JOURNAL, December 9th, 1922) it was said: " will agree with Professor Crile when he states that we w first of all to express our sense of the obligation of medic to Theodor Kocher in Europe for the secure foundat laid by him for surgery of the thyroid gland." Again, the *British Journal of Surgery* (1926, No. 51) G. Sc Williamson said that the term "*thyrotoxicosis*" (Koch is preferable to "forme fruste." I will add one furth illustration of a waking conscience from the youngest a latest journal, *The Leech*, of the Welsh National School Medicine, in which no fewer than nine pages (Octob 1926) are devoted to thyrotoxicosis, and due appreciation shown of the master's work.

Water Supply.

We learn from the letter which I have just read th Theodor Kocher showed himself a scientific seer as long a as 1889, when he indicated at a popular lecture his vi that the cause of goitre was in water, and urged "t Government to have the drinking water in the pub schools boiled, or to add iodine to it, to prevent goitre It is evident that the late battle-ground regarding the c

iodine and its appraisement in surgical cleanliness has been shifted to the medical preventive side in relation to goitre among school children. The value of the letter will become apparent when I read an extract from a very notable contribution on the thyroid gland by Charles H. Mayo and Henry W. Plummer, published in 1926, and described in the preface by the chairman of the Beaumont Foundation Committee as the most authoritative pronouncement upon the subject ever given: "At the time of his (Kocher) death in 1917 approximately 5,000 cases of goiter had been operated on at his clinic. In 1917 the practical application of a method to prevent simple goiter was started in the public schools of Akron, Ohio, by Marine and Kimball." There is a reference to a somewhat similar plan in my review, already referred to, of Crile's book, where recalled the fact that Kocher held goitre to be water-borne, due to "a hitherto unknown micro-organism, or more probably a chemical agent . . . made inoffensive by boiling the water. That is why he proposed, forty years ago, to boil all the drinking water, especially at the schools, to prevent goitre. But at the same time . . . he proposed to give the children twice or three times a year during some weeks a small dose of iodine to prevent goitre. He had then a malt preparation made with iodine and iron." This preparation he gave to his own three sons three times a year. "The result is that [the] three brothers have absolutely normal thyroid glands." (BRITISH MEDICAL JOURNAL, 1922, ii, 1123.) It is interesting to recall that in 1854 it became known that cholera was a water-borne disease, although the actual cause was not then discovered; we are to-day in a somewhat similar position with regard to goitre, but are very near the goal.

Incidence of Goitre in Wales.

I had hoped that the inquiry instituted by the Ministry of Health into the incidence of goitre in our country would have been ready before this, as it would have been of great interest, but unfortunately I heard from Sir George Newman, who has given me much help, that the memorandum on the subject had not yet been published. It is now over twenty years since the late Dr. Williams, M.O.H. Glamorgan, and I instituted an inquiry into the incidence of goitre, and received replies from 231 medical practitioners. In a paper read before the Medical Society of London on April 22nd, 1907, I reported that "as far as I can judge from analysis of the evidence collected, the distribution of goitres in Wales and Monmouthshire supports the view that the causation of this disease is to be found in drinking water."

Goitre is found in almost every country in the world from sea-level to 10,000 feet above, wherever soil exists for man to live on. In Wales it is fairly common in counties bordering the sea, and also in patches inland—for example, Gwendraeth valley, Llanidloes, Vale of Clwyd. It is found on soil which covers rocks a million, ten million, or a hundred million years old; the chemical composition of the geological formation is apparently of little importance—the surface soil is the only factor left that counts.

Goitre is fairly common over the ordovician rock in Cardiganshire, where, in cuttings or quarries, the mother rock may be covered with a crushed layer, called "rab" locally—evidence of the weight and direction of the enormous ice sheet that ground and rounded off the general contour of the land. There is often very little soil over the "rab"; the rock is notoriously deficient in lime salts, but goitre is not uncommon.

The Cause of Goitre—Micro-organism, Iodine Deficiency, or Endocrine Imbalance?

Evidence is accumulating so strongly, that one of Kocher's double-barrelled predictions of "the unknown organism" as the cause of goitre will, I think, shortly be fulfilled—for example, that from the Mayo Clinic: "Rosenow has isolated an anaerobic *Gram*-positive diplobacillus-like organism from the excised thyroid gland in twenty-five of thirty-two cases of goitre." "Of the sixty-eight animals injected with strains from sixteen patients (ten with exophthalmic goitre and six with non-toxic goitre) and examined soon after injection, thirty-four (50 per cent.) developed gross lesions in the thyroid."

The part iodine plays in the etiology of goitre I leave in the able hands of Colonel McCarrison, I.M.S., whose valuable work on the etiology of goitre is well known, and who has now in the press a report of his experience at the Lawrence Royal Military School, Sanawar, Punjab, India, which, in its precision, almost amounts to a scientific experiment. The work was commenced in 1913, and observations have been continued ever since. [The story is told in the paper by Colonel McCarrison published in this issue at page 94.]

Upon this aspect of the subject I have consulted Professor H. J. Fleure of the University College of Wales, Aberystwyth, whose knowledge, alike of the geology and anthropology of Wales, is unsurpassed. He writes:

"While we have made observations as conscientiously as possible on goitre, I cannot say that they have led to any very clear conclusions as to any one particular cause. We find that the administration of iodine has been undoubtedly valuable in a number of cases. It has been given in the form of iodized table salts. Whether the importance of this is the direct contribution of iodine to the system or whether the iodine acts as an enemy to some factor of the disease, we do not presume to say. Alongside of this we have found the insistence on boiled water very important, but whether this implies that the disease is connected with some filter-passing germ or of some chemical which is altered by boiling, we do not know. There is no doubt that, along with curative measures such as the above, it is very important to take measures to maintain and develop the resistance, and this is done in two ways. In the first place, therefore, attention should be given to the teeth, which for some reason which needs investigation are notoriously bad in West Wales. In the second place, Miss Fleming has urged the use of an improved vegetable and fruit diet, including fruit and fresh greenstuffs. The fruit is chiefly apples and oranges. We cannot but think that one of the problems involved is some question of a balance of endocrine secretions, and this is apparently very liable to be altered by inbreeding, so the troubles connected with this alteration of balance are specially abundant among the peoples of isolated districts."

Details in Operative Technique.

Before concluding my somewhat discursive remarks I venture to draw attention to the importance of carrying out some details in operative technique which facilitate work and give the best results in most operations on the neck and specially those for goitres.

The first is to follow the direction of Kocher's collar incision in all operations on the neck, whether small or large, and to avoid making a longitudinal incision; in this way a hazardous bloody operation is converted into a practically bloodless one without any risk of injury to nerves, for the surgeon sees every step before moving on.

The second is to place the patient in what I described in 1907 as the "Albert Kocher" position, which means a semi-recumbent or anti-Trendelenburg position, by which the superficial veins of the neck are converted into empty flat tubes during normal respiration.

The third is to remove sutures or clips and drainage tube within twenty-four hours after operation; this avoids all scarring beyond the inevitable thin white threadline left by the collar incision. It is perfectly safe to remove silk sutures—to which I am biased, by imitation of Kocher—but it is necessary to remove only an inch at a time, then secure apposition by fixing half-inch wide gauze strips with collodion crosswise to the collar incision. In order to avoid any possible risk of the buried subcutaneous portion of the silk suture, it is wise to paint the skin beforehand with iodine, then pull gently on the suture to enable the surgeon to cut the portion that was subcutaneous, thus avoiding withdrawal through the wound of the exposed portion of the silk suture, which is of the finest size for the smallest skin-needle.

Lastly, it is important in operations to mark the skin at right angles, in two or three places, before making the incision, according to its length, to serve as landmarks in restoring the skin and subcutaneous tissues to their normal disposition. I described the method in a paper read before the Medical Society of London in 1907, but as I did not explain how the idea originated, I do so now to illustrate how an idea sometimes starts from an accident. Of the 73 operations recorded, 55 were performed under local and 17 under general anaesthesia. In the remaining case no anaesthetic was employed owing to breaking of the hypodermic syringe, and I proceeded with the operation by transfixing the skin after the fashion of pre-anaesthetic days. After finishing suture of the skin with continuous

silk I discovered that a mole had been divided and that the sutured halves were at least half an inch apart. I removed the suture in order to restore the mole, which subsequently formed a landmark. I copied this hint and applied it in every operation afterwards; it is of some practical importance, more especially in the restoration of skin to the normal; the surgeon quickly realizes by marking the skin with the point of a needle (Moynihan) how almost impossible it is to get normal alignments without skin landmarks.

Arthur Keith, discussing the law of collateral or "uniform evolution" "as certainly valid for the order of animals to which man belongs," says he does not think it possible that the

"Mongolian stock had arisen from an anthropoid of the orang type, while the African negro had drawn his origin from the ancestral type of the gorilla . . . there are certainly superficial points in which the Mongolian type resembles the Bornean anthropoid, . . . Cretins of all races are alike. They cease to be Europeans or Asiatics in appearance. Cretinism is the result of a defect of the thyroid gland: . . . so potent is this gland in fashioning the features that a cretinized English child might be taken, by a superficial observer, as brother to a Chinese cretin. It is also so, when the pituitary gland becomes disordered. . . . The glands of internal secretion are parts of the machinery of evolution, not only of man but of apes. The resemblances of the orang to the Mongolian type are due to thyroid dominance in the action of their glands of internal secretions." (*Antiquity of Man.*)

The youthful Dr. Rip Van Winkle who went up the Catskill Mountains in 1883 came down to-day to find strange things to convey his successor to consultations by road and by air; he read strange records of the value of x rays, radium, and cardio-electrography in Graves's disease; but the strangest thing of all was to listen to a wireless discourse from the wonder hospital which had grown in thirty years from a cottage hospital with a staff of three to that of a University Medical School with a staff of 301—the far-away Mayo Clinic—on the revelations in the physiology of the thyroid gland, and on revolution in the surgery of goitre, carefully engineered and successfully launched from Berne.

AN EXPERIMENT IN GOITRE PREVENTION.

BEING

THE FURTHER HISTORY OF GOITRE AT THE LAWRENCE ROYAL MILITARY SCHOOL, SANAWAR, PUNJAB, INDIA.

BY

ROBERT McCARRISON, C.I.E., M.D., D.Sc., F.R.C.P.,
LIEUT.-COLONEL, I.M.S.,
DIRECTOR, DEFICIENCY DISEASES INQUIRY, PASTEUR INSTITUTE, COONOOR, SOUTHERN INDIA.

IN a report on the causation of goitre at the Lawrence Royal Military School, Sanawar, Punjab, Northern India, submitted to the Indian Research Fund Association in 1914[1] it was shown that the disease was not due to any chemical substance (lime, magnesium, etc.) in suspension or in solution in the water supply. The conclusions were drawn that goitre in Sanawar was due to the presence of living micro-organisms in the water supplied to the children for drinking purposes; and that the disease could be eradicated by the provision of a chemically and bacteriologically pure water.

Goitre had been endemic in Sanawar since the foundation of the school in 1848. So great was its prevalence that in some years as many as 50 per cent. of the children suffered from it; while after a residence of eight years in the school about 80 per cent. became goitrous. At the time my investigations were begun (1913) no less than 66 per cent. of girls above the age of 16 years were the subjects of noticeable goitres. Many of the swellings were slight and some of them transitory, but a high proportion were true goitres (not merely physiological swellings) which caused noticeable disfigurement. Full details regarding the incidence of the disease and the investigations which led to the above conclusions will be found in the report referred to.

Following the recommendations made in this report a new pipe water supply, from the neighbouring station of Kasauli[1] was provided in 1918. Thereafter goitre began to diminish and has now disappeared. Captain P. Sav I.M.S., the present medical officer of the school, i letter to the principal, of which a copy was sent to m January 30th, 1926, writes:

"One year's experience has convinced me that goitre is entirely absent. I have not seen a single case, and I propo mention in my annual report that goitre can now be consi a thing of the past."

Similar reports were received from previous me officers. Thus one states, in a letter dated June 1921:

"There have been no fresh cases of goitre noted this The disappearance of goitre is probably due to the fact tha water supply was changed from the Sanawar spring to Kasauli supply. This fact was intimated to the Inspector-Gen Civil Hospitals, Punjab."

Again, on October 17th, 1921, the Assistant Directo Medical Services in India reported that "Since Kasauli water supply has been piped to Sanawar there been a complete absence of goitre."

In the autumn of 1923 I revisited the school, with object of seeing for myself what was then the incidenc the disease. I found one boy, aged 16, who had still enlargement of the thyroid, and ten girls, at or over age of puberty, who were the subjects of small goi some barely noticeable. The remaining 489 children free from goitre. The incidence of the disease was 2.2 per cent., or no greater than the incidence of thy enlargement among school children residing in non-end areas[1] such as Delhi (2.2 per cent.), or Kasauli, which the new water supply was derived (2.4 per ce It was no greater, also, than in another Lawrence R Military School in Southern India, at Lovedale in Nilgiri Hills. This school is situated in a region w the iodine content of the soil is very high (300 to 400 per 10 millions); at a recent examination of 452 of children I found ten cases of visible goitre, involving lobes and the isthmus, in 162 girls; and one case an 290 boys. Of these eleven cases two were in girls who acquired the swelling at the Sanawar school. It had disappeared following their transfer to the Lovedale sc My experience has been that in any community of sc children there will always be found a greater or sm number of thyroid swellings which bear no relation w ever to endemic influences.

It is clear, then, that goitre, which had been end in Sanawar for seventy years, has now disappeared; that its disappearance has been due to the introductio a new and protected water supply. Its eradication wi the short space of three years is, so far as I am aw unparalleled in the history of goitre prophylaxis. Sim instances are to be found in the literature,[2] but non which the endemic has been so carefully followed thro out its whole course nor in which the measures dec upon for its eradication have followed more exhaus study of the local conditions.

The new water supply may have caused the disappear of the disease either because it increased the iodine int of the scholars or because it was a bacteriologically water, whereas the old supply was grossly contaminat I have the assurance of the principal, contained in letter of May 9th, 1923, that "no changes of any im tance were made in the diet between 1914 and 192 There was, therefore, no increase in the iodine intake way of the food. Consequently, the question to be dec was whether or not the new water supply contained n iodine than the old. The Chemical Examiner, Punjab his report on the new water supply, dated March 1 1922, stated that "The sample is of very good qua chemically and remarkably free from impurity. It cont only traces of lime and magnesium and no iodine." I t caused 25 gallons of the new supply, as delivered by at Sanawar, to be evaporated to dryness after the addi of sodium carbonate. This was done under the su vision of the Director, Central Research Institute, Kas (Lieut.-Colonel S. R. Christophers, I.M.S.). The resi was sent to the Chemical Examiner, Punjab, for esti tion of its iodine content. In his report, dated August 2 1923, he stated that iodine was not detected in any f in the residue.

The recent work of Fellenberg, McClendon, Hereus, and hers, having emphasized the difficulties attendant on the timation of iodine in soils and water, led me to think at more refined methods of analysis might possibly veal significant differences in the iodine content of the o waters. Accordingly on my return to India in 1925, as to settle the matter finally, I secured the co-operation three chemists: Major C. Newcomb, M.D., F.I.C., M.S., Chemical Examiner to the Madras Government; r. B. Viswanath, F.I.C., Agricultural Chemist to the adras Government; and Dr. R. V. Norris, D.Sc., Prossor of Biochemistry, Indian Institute of Science, Bangare. Each undertook to examine independently the pubshed methods of iodine determination in soil and water, id to select the method which he found gave the most liable results or to evolve another for himself. While eir preliminary investigations were in progress I btained, through the kindness of Captain P Savage, M.S., medical officer of the school, and of Lieut.-Colonel . Cunningham, I.M.S., Director of the Pasteur Institute India, Kasauli, samples of soil and of water concenates from both Sanawar and Kasauli. The concentrates the old and of the new water supply were prepared, ith minute attention to detail, by Colonel Cunningham, fter the manner recommended by McClendon. Meanwhile ach of the three chemists had evolved a method of iodine stimation which appeared to be satisfactory; their ethods, however, differed in detail. The samples of soil nd water concentrates were then sent to them at Madras, oimbatore, and Bangalore respectively; each chemist eing unaware of their source. The results are given n the table.

Sample.	Iodine Content in Parts per 10,000,000.		
	I.	II.	III.
)ld water supply of Sanawar school	1.0	Trace	Trace
Vew water supply of Sanawar school ...	1.0	Nil	Nil
Sanawar hillside soil	35	16	30
Sanawar garden soil	8	5	30
Kasauli hillside soil	45	32	10
Kasauli garden soil	10	4	0

Column I, Major Newcomb's results; Column II, Mr. Viswanath's results; Column III, Dr. Norris's results.

The details of the methods of iodine determination adopted by the three observers will be given in a future report on the relation of iodine in soil and water to goitre, when the various technical difficulties and sources of error will be dealt with by them. Meanwhile it may be said that their results, arrived at independently, show a close correspondence and a general agreement* in regard to the following points with which this paper is mainly concerned:

1. The soils and waters of both Sanawar and Kasauli are poor in iodine.
2. There is no significant difference in the iodine content of the soil in the two places.
3. The old water supply of the Sanawar school contains appreciably more iodine than the new, which contains little or none; thus confirming the previous reports of the Chemical Examiner, Punjab, in regard to the new supply.

It is obvious, therefore, that the disappearance of goitre from the school cannot be attributed to the presence of iodine in the new water supply.

The conclusion arrived at in my first report, that endemic goitre in the Sanawar school was due to the bacteriological impurity of the old water supply, is thus substantiated; and the prediction that it could be eradicated by the provision of a chemically and bacteriologically pure water supply has been justified by the disappearance of the disease.

*The differences in the results of the three observers are not significant; they fall within the limits of experimental error.—R. McC.

CARCINOMA OF THE COLON.

AN ADDRESS GIVEN TO THE GLOUCESTERSHIRE BRANCH OF THE BRITISH MEDICAL ASSOCIATION

BY

R. P. ROWLANDS, M.S., F.R.C.S.,

SURGEON TO GUY'S HOSPITAL.

THE results of primary operation for carcinoma of the colon are good, contrasting favourably in this respect with cancer of the stomach or rectum. It generally kills by causing intestinal obstruction, and if we avoid this by removing the growth at an early stage the hope of cure is a good one. The disease usually originates as an ulcer or occasionally as a papilloma. It spreads slowly in the wall of the bowel and takes a long time to infect the lymphatic glands or to invade the liver through the portal vein. Mr. F. T. Paul[1] has pointed out that there are three main types of this disease. I will quote his words.

"The three varieties of carcinoma are: (1) The large soft fungating 'encephaloid' type; (2) the small hard 'scirrhous' type; and (3) the infiltrating 'colloid' type. All may be said to be primarily columnar-celled growths originating in the intestinal glands, and all ulcerate; but they follow different paths of evolution, and attain different degrees of malignancy which it is important to recognize. The scirrhous variety is always unmistakable. It produces the hard ring stricture of the bowel, and is more common than colloid cancer, but much less frequent than the soft fungating type. This latter may usually be as easily distinguished from the colloid form of growth by the following characters: It is softer to the touch. There is a good deal of fungating growth within the bowel, but generally not much solid infiltration of the bowel wall. There are usually numerous large soft glands in the neighbouring mesentery, which are septic and not malignant. In colloid cancer, on the other hand, there is a hard-edged ulcer with no fungation. There is dense hard infiltration of the bowel wall, often attaining a thickness of from one to two inches, and giving it a solid feel. The glands, if affected, are not soft, but hard and glistening. . . .

"*Misconceptions Regarding Cancer.*— . . . The really important misconception, however, concerns the relative malignancy of the three varieties of cancer. Usually the big, fungating, encephaloid type of growth is regarded as the most malignant; the colloid as being intermediate, and the scirrhous, or ring stricture, as the most benign. This arrangement is entirely wrong and out of accord with clinical experience. The colloid is the most malignant type, the ring stricture comes next, and the fungating type is the best—it being one of the least malignant kinds of cancer met with in the body.

"It is a clinical fact of considerable importance, to which I have often referred at our local medical society, that the upgrowing forms of cancer are essentially less malignant than the down-growing, ulcerating and shrinking types.

"The most common sites for the fungating type of growth are the rectum and caecum, though it often occurs in the sigmoid, and occasionally at any other part of the large bowel. Colloid cancer chiefly selects the rectum, and ring stricture the sigmoid, though neither is limited to these regions."

SYMPTOMS AND SIGNS.

The symptoms and signs are insidious in their onset and generally develop in a patient approaching, at, or over middle age. They consist of "indigestion or flatulent dyspepsia" of the intestinal type, with alternating diarrhoea and constipation; there are many urgent calls, with more or less futile attempts, to empty the bowels; naturally formed motions are rarely passed, but small pieces with, perhaps, blood and slime. Occult blood is generally found when the patient has been for some days on a meat-free diet. The abdomen gets somewhat full and distended, colicky pains are frequent and are associated with visible peristalsis. A tumour is often felt on bimanual examination of the loin or pelvis, but it is difficult or impossible to feel a growth of the splenic flexure.

Radiographic examinations after opaque meals or enemata are often of great value, especially if the findings are constant and repeated, but there are many fallacies associated with this method. Examination with the sigmoidoscope is far more reliable as regards the part of the bowel that is within its reach, but the instrument has to be used with care and discretion. In many early cases the diagnosis cannot be established without exploratory operation, and this should be undertaken whenever there is grave doubt, for it allows the growth to be removed in its early and hopeful stage.

When chronic obstruction is succeeded by acute, often the result of inflammation or plugging of the stricture by

a scybalum or sometimes by a faecalith, the abdomen becomes greatly distended, but its shape and size are very different from those due to obstruction of the small intestine, one or both flanks being full and prominent. The size and shape of the caecum become evident during spasm and pain, and other parts, such as the transverse or sigmoid colon, may become visible during colic. The patient himself may point to the site of the obstruction, having noticed pain, and especially gurgling, at a particular spot, or the medical attendant may make this observation.

DIAGNOSIS.

Cancer of the colon is often mistaken for other diseases of the colon, especially ulcerative colitis, dysentery, and sprue. We ought to be very uneasy about the diagnosis of chronic colitis, and always seek the cause of it by thorough examinations. Many patients who have been treated for one or more years for ulcerative colitis come at last to the surgeon too late for radical operation; the same is true of dysentery and sprue.

Diverticulitis of the pelvic colon mimics carcinoma to a remarkable degree, but in this disease there is usually a history (sometimes of over twenty years) of recurrent attacks and fever, with incomplete obstruction and pain, perhaps swelling, in the left iliac fossa. There is rarely any history of blood and slime, and careful radiographic examinations after opaque meals and enemata demonstrate the presence of diverticula in the colon. The most conclusive evidence is the finding of opaque spots in the bowel after the meal or enema has been evacuated, some of the opaque material having been retained in the diverticula. In the interval of the attacks these patients are often quite well. The diagnosis is most important, for operation is not always the best treatment for diverticulitis. It is possible, however, for the two diseases to coexist, as actually happened twice in my experience.

Papilloma and adenoma of the colon may be mistaken for carcinoma. One of my patients, a middle-aged woman, had severe remittent rectal haemorrhage on and off for nineteen years; when at last operation was performed there were five papillomata of the pelvic colon, one of which had become carcinomatous at the base.

Appendicitis with chronic suppuration has not uncommonly been mistaken for carcinoma of the caecum or ascending colon, but here there is usually a definite history of acute and sudden onset of pain with fever. In some cases exploration is necessary to settle the diagnosis.

Tuberculosis of the caecum, forming a massive swelling, sometimes simulates carcinoma, and so does volvulus of the pelvic colon, causing acute obstruction. In several cases where I expected to find carcinoma of the colon I fortunately only found pericolic bands, division of which brought cure. In some instances a gall stone, impacted in the narrow pelvic colon, has been mistaken for cancer, and in some a faecalith has led to the same mistake.

In old people ordinary faecal impaction with irritating diarrhoea has often been mistaken for cancer, but the mistake is easily discovered upon examination of the rectum and finding scybalous masses there. Rectal bleeding due to other causes has led to error. For instance, I remember a man who had very severe rectal haemorrhage, causing him to faint; sigmoidoscopy some days later showed blood in the pelvic colon and an apparent stricture. Carcinoma of the colon was diagnosed, but this diagnosis was not confirmed at the exploration; the source of the bleeding was found to be internal piles, which were successfully removed.

Almost any other abdominal tumour may be mistaken for carcinoma of the colon, or vice versa. I recently mistook a distended and very large gall bladder, measuring eight inches in length, for a growth of the caecum and ascending colon, but the absence of serious intestinal symptoms, and especially the history of previous attacks of biliary colic, should have prevented this mistake.

The diagnosis is not complete until it has been ascertained whether the growth is removable, therefore it is vital to look for signs of secondary growth in the liver and peritoneum. Rectal or vaginal examination often discovers secondaries in the pelvic peritoneum, rendering a radical operation impracticable. Before advising such a severe operation as removal of cancer of the colon it is also necessary to ascertain the state of the general health and of the viscera, especially of the kidney.

TREATMENT.

1. The ideal is to discover the growth early and remove it without delay, thus to cure the patient at one operation. End-to-end union, after removal of the growth, is nearly always the best and most economical, but for growths of the caecum, ascending colon, and hepatic flexure, for which the lower six inches of the ileum, the caecum, and the right colon have to be removed in order to effect a cure, it is better to make an end-to-side union between the ileum and transverse colon.

To attain success in these resections careful preparation of the patient, accuracy in sewing, perfect haemostasis, scrupulous cleanliness, and free drainage are essential. In order to drain the colon freely and prevent gaseous distension and undue tension upon stitches it is sometimes necessary to add caecostomy or to use a rectal tube passed up into the colon through the anastomosis.

CASE 1.

A medical man, aged 48, was one of nineteen children. His father and one brother died of cancer of the bowel. He himself had suffered for years from piles from which bleeding had often occurred. For the last two years there had been a good deal more bleeding from the bowel, and this had often been associated with pain in the left iliac region. In March, 1910, the bleeding became more severe and came on quite apart from defaecation. He gradually got into poor health and wasted a good deal, and a fortnight before I saw him he fainted. Mucus and much blood escaped from the rectum. The patient saw several consultants and was referred to me for operation on October 19th, 1910.

I felt an elevated growth high up in the rectum. I could not find any stricture, but only what appeared to be an ulcer occupying one side of the bowel. During the examination the growth receded out of reach, clearly showing that it was fairly high in the bowel but had intussuscepted into reach. Then the receded growth could be felt through the anterior wall of the rectum. It was thought that an abdomino-anal resection would be the best operation.

The bowels were well cleared out and the patient was kept at rest for three days and carefully prepared on a diet leaving little residue. Morphine, gr. 1/3, and atropine, gr. 1/150, were injected an hour before the operation on October 22nd, 1910, and axillary saline infusion was also commenced and continued during the operation, five pints in all being given. Open ether was administered by Mr. Plumtre. The abdomen was opened through the lower and inner part of the left rectus and the growth was at once found in the lower part of the sigmoid loop about nine inches from the anus. It was freely movable, and some enlarged glands were felt in the meso-sigmoid. The liver and lumbar glands were normal. The high Trendelenburg position was adopted, and it was decided to resect the growth abdominally and join up the colon end to end. This was carried out, nine inches of bowel and the lymphatic area being removed. Microscopic examination of the enlarged glands showed inflammatory changes only. End-to-end union was performed with two silk sutures. The first was a continuous Connell and the second a continuous Lembert suture. The packs were removed and the rent in the mesentery was closed as far as possible with catgut sutures, and the bowel was replaced. The peritoneum was cleansed of blood and the wound was completely closed in layers. The operation lasted an hour and a quarter, and at the end of it the patient was not collapsed. On opening the piece of bowel removed it contained no faecal matter, only a little blood-stained mucus. An ulcer, two inches long and one and a half inches wide, with rampart-like edges was seen; the mucous membrane around it was much congested and inflamed. The ulcer did not encircle the bowel or appreciably narrow the lumen; it had clearly obstructed and caused pain only by intussusception. There were very few enlarged glands in the mesentery, except quite close to the growth, which was a columnar-celled carcinoma.

The patient did very well; the wound healed without any trouble, and he left the home within a month. He was at work in his busy practice within two months of the operation. He remained well for thirteen years and then died of an acute abdominal catastrophe—probably ruptured duodenal ulcer.

2. If obstruction has already developed an attempt should be made to overcome this by rest in bed, restriction of diet, and the use of enemata, but too much time must not be wasted on this endeavour. If enemata are successful the patient may be carefully prepared, as above, for a one-stage radical cure; but if the bowels refuse to act, prompt relief by operation must be given.

(*a*) *Caecostomy.*—In very grave cases, when the distension of the caecum is visible, blind caecostomy (Stiles) may be performed under local or general anaesthesia. This is practically devoid of risk. Subsequent examinations may reveal the cause and site of the obstruction and a secondary

operation may be successful in removing or short-circuiting the growth. In most cases of acute obstruction, however, ıe cause and site are not clear, therefore an attempt to ɔrform a blind caecostomy may be disastrous. As already entioned, the colon may be obstructed by bands, volvulus, · foreign bodies inside it; in one famous case a medical an suffering from acute obstruction was first explored in ıe left loin, in an attempt to perform left lumbar colo-omy, but the descending colon was empty; a similar ıtempt on the right side was also futile, the ascending ɔlon being empty. The patient died on the table, and ; the autopsy the cause of obstruction was found to be a all stone impacted near the lower end of the ileum. For ıese reasons I prefer to explore the abdomen, very care-ully and gently, under light general anaesthesia, with ıe hand introduced through an opening in the right iliac ɔgion only just large enough to admit the folded hand. he liver is examined for secondary growths, the site and ıuse of the obstruction is discovered, and, if it be a rowth, its removability is ascertained. While doing this, ı a recent case, the caecum was discovered in the splenic rea, showing how futile a blind caecostomy would have een. If there are no secondary growths and the primary arcinoma is removable, valvular caecostomy is performed, ut if there is no hope of resection, either a short-circuit r a colostomy is made, for caecostomy as a permanent ieans of draining the bowel is intolerable, on account of he frequent and irritating fluid actions. As a rule it ; worth while to run a slightly greater risk in these cases n order to avoid an artificial anus.

(*b*) *Colostomy* is better than caecostomy for certain ases: (1) when the growth is irremovable and short-*circuiting is* impracticable, as mentioned above; (2) when he obstruction is low down in the colon For instance, hen the growth is in the pelvic colon and the bowel just bove it is greatly distended and more or less paralysed, aecostomy does not provide sufficient drainage, so that the lescending colon remains full and inflamed for several veeks, making it *difficult or impossible* to perform a satis-actory secondary resection. Therefore in these cases a olostomy, slightly above the growth, is the best preliminary reatment.

(*c*) *Short-circuit.*—As already mentioned, this is very uccessful as a permanent measure when the growth is irremovable. It is also valuable in some cases when the bstruction is not too severe and the patient is fairly fit. For instance, a lady with a growth at the splenic flexure, ausing complete obstruction for a fortnight, was treated by making a short-circuit between the middle of the trans-erse and pelvic colon. Nearly two months later the growth, which had shrunk to half its former size, was successfully excised, the patient remaining well now, six ears later. In this case the resection was made easier and safer by the preliminary short-circuit, there being no need to make an anastomosis but only to tie and invert the ends of the colon near the one already made.

(*d*) *Primary Resection after the Method of Paul.*—Whereas it has been proved that primary resection with restoration of the natural channel is very dangerous treatment for acute and complete obstruction of the colon, the mortality being well over 50 per cent., it has not been sufficiently appreciated that the danger lies not so much in the removal of the growth (provided it is well and swiftly done), but rather in the union of soft, inflamed, and damaged tissues, which too often in the past led to leakage at the line of suture, which cannot stand any gaseous or faecal distension. When free drainage is provided the resection and even reunion may not be too dangerous. In many acute as well as chronic cases the method of Paul (often wrongly called that of Mikulicz) is safe, the growth being removed and the ends of the colon above and below being drained with Paul's tubes. The artificial anus thus made may close spontaneously or be closed later by a comparatively safe minor operation.

The chief objection to this method, which is rarely suitable except for mobile pelvic or transverse colons, is that the lymphatic glands cannot be widely removed. In spite of this, however, very good permanent results have been obtained.

CASE II.

A married woman had suffered for many years from constipation, which during the last few months had been getting worse; no blood or slime had been noticed. In the middle of December, 1910, she was seized with severe abdominal pain; the bowels were not opened and she passed no flatus. During the following fortnight the patient was kept in bed and was given opening medicine without avail, generally vomiting it; she had one enema without effect. She took little food and had very little sleep. At the end of the fortnight the pain and sickness were better and she was sent to Guy's Hospital. The abdomen was greatly distended and three times during half an hour visible peristalsis could be seen about the position of the caecum. The patient was then suffering from severe colic. She had shifting dullness in the flanks. The abdomen was neither tender nor rigid. The temperature was subnormal. Chronic intestinal obstruction, due to growth of the colon, was diagnosed, and it was thought probable that it was somewhere about the transverse colon. Rectal examination revealed no growth in the pelvis.

Operation.

On January 2nd, 1911, the abdomen was opened by displacing outwards the lower part of the right rectus. The caecum was at once seen to be distended, and the small intestines were also very distended. A large amount of clear fluid escaped from the abdomen. On passing the hand into the pelvis a growth was felt about nine or ten inches from the anus. It was a small contracting carcinoma. The bowel above it was greatly distended. It was seen that, although it would be possible to make an anastomosis between the ileum and the bowel below the growth, it would not then be possible to perform a secondary resection of the growth. Moreover, the patient's condition was bad. Therefore a small muscular separation incision was made in the left flank, and a loop of bowel containing the growth was brought out through this wound and fixed in position by means of a Spencer Wells forceps passed through the mesentery and clamped on a pad. The incision was then closed and covered with a sealed dressing. A roll of gauze was wrapped round the base of the loop of sigmoid, and then a Paul's tube was tied into the distended bowel, one inch above the growth. The patient was infused about four pints during the night. She made very rapid improvement and regained her natural colour, her face becoming much fuller. She ate and slept well.

Five days later, on January 7th, the growth was removed with the cautery, the lower limb being divided first about two inches below the growth, then the mesentery, a wedge of which was removed, and lastly, the bowel, about three inches above the growth, was divided. The vessels were tied and the two ends of the bowel were sewn together, starting at the mesenteric border and proceeding in each direction towards the free border, leaving an aperture just large enough to admit a small Paul's tube, which was tied in. Two days later the tube was removed.

About three months later, the colostomy not closing, an operation was done to close it and to remove the glands more freely, but unfortunately a pelvic abscess formed and had to be drained, with the result that all the faeces escaped at the wound and none through the rectum. After some weeks the patient was discharged, to come in later for further treatment, but, at the end of three months, she cured herself by passing a bougie through the anus and rectum into the pelvic abscess. From this time the bowels began to act naturally and the wound healed. She was seen, in good health, eleven years later.

(*e*) *Resection with Drainage by Rectal Tube.*—In some cases, when the growth is in the pelvic colon, primary resection may be carried out with safety, provided the upper bowel is well drained by a rectal tube passed up through the anastomosis.

CASE III.

A man, aged 51, came to see me on April 29th, 1918. He had not had his bowels open for eight days. He had suffered much pain in the abdomen and was more or less collapsed, with a subnormal temperature; he had not vomited, but had felt very sick. He also had a distended abdomen, and the bowels could be seen through the abdominal wall to be in violent peristalsis. He was particularly shrivelled and thirsty because he had abstained from both drinking and eating more than a minimum for three or four days, showing wonderful strength of mind. This had brought him into a very low state. On examining by the rectum I could feel a hard lump in the recto-vesical pouch, between the bladder and the rectum. This was thought, and proved, to be a growth in the dependent loop of the pelvic colon. More enemata were tried without success, and the next day an incision was made to the left of the mid-line, the loop of colon containing the growth was brought out of the wound and the greater part of the pelvic colon, with its mesentery, removed. End-to-end union was made. Then a long tube was passed up into the colon above the anastomosis and sewn to the skin near the anus.

The patient did well, returning home three weeks later. He was heard of as being in good health eight years later.

After-Treatment.

The after-treatment of patients submitted to colectomy is just as important as their preparation before the operation. The commonest error is the too early and too frequent use of purgatives, whereas the ideal is to let the bowel rest in peace. As soon as possible I give half to one ounce

of pure liquid paraffin morning and evening and get the patient on full diet, generally within three days of the operation, with the result that the bowels usually act normally after three or four days. Sometimes the action is delayed without any harm. Occasionally it is necessary to run olive oil into the rectum through a soft catheter. No strong purgative or ordinary enema is given.

DARTMOUTH.

THE ESSENTIAL OIL TREATMENT OF CHOLERA.

BY

ALEXANDER CANNON, M.B., CH.B.LEEDS,
CANTON.

RECENTLY Dr. Tomb introduced in the Asansol Mining Settlement, Bengal, a treatment of cholera by an essential oil mixture made up as follows:

Spt. aether.	m xxx
Ol. caryoph.	m v
Ol. cajap.	m v
Ol. jump.	m v
Acid. sulph. aromat.	m xv

One drachm, in half an ounce of water, to be taken every half-hour (in case of cholera); total average dose 8 drachms. One drachm, in half an ounce of water, daily, is an excellent preventive.

This mixture should be given immediately, when practicable, but it is claimed (and here it has been proved) that in 95 per cent. of cases recovery will be secured within a period of seven hours from the onset of symptoms. No special care need be paid to subsequent dieting. Vomiting, purging, and intestinal pains appear to be immediately controlled by this mixture. As little supervision is requisite, the value of the method in mass treatment of natives is obvious.

Manson-Bahr and others state that the cholera vibrio may be found in the stools for as long as forty-four days after the patient has commenced convalescence. Bacteriological examination so far shows that following the administration of Dr. Tomb's mixture the vibrio ceases to exist after a period of from six to twelve hours from the commencement of the treatment, thus apparently reducing the quarantine period from forty-four days to twelve hours. This is a matter of considerable importance from the shipping point of view, as it is not necessary to keep a ship in quarantine for more than twelve hours, since everyone on board (passengers and crew) can be treated as a potential cholera case and given a dose of the mixture every half-hour for four hours (which is sufficient to cure a case of cholera, seen within seven hours of the first symptoms, up to 95 per cent. recoveries, and practically 100 per cent. if given as soon as symptoms appear).

I have bacteriological proof that this mixture can also clear up a case of typhoid fever within twenty-four hours, which is a matter worth investigating, as this might prove an infallible mixture for those diseases where the germ is present in the intestines, etc.

The few cases of cholera we have had here had not taken the essential oil mixture once a day as a preventive. Most of these, when first seen, had marked choleraic symptoms with the typical rice-water stools, and on bacteriological examination, which in some cases was confirmed by Surgeon Commander R. Buddle, R.N., the cholera vibrio was found to be present, and in large numbers, in every case. Only one patient died, and he refused treatment until twenty-four hours after symptoms appeared, when I was called in to see him for the first time. He was in the algid state, and before an intravenous saline injection could be given he died. All other cases recovered in from seven to twenty-four hours of commencing treatment; those recovering in seven hours had immediately resorted to the treatment, and those who took longer to recover had awaited until their symptoms were so marked that treatment had to be strictly enforced. I append a few brief notes of cases.

Case 1.—A man, aged 35, had violent cramps, vomiting, and rice-water stools. On microscopic examination the cholera vibrio was found to be present. The essential oil treatment was given within two hours of the commencement of symptoms. Six hours later no vibrios were to be found.

Case 2.—A man, aged 32, had symptoms similar to those of Case 1, but no vomiting. Microscopic examination showed the presence of the cholera vibrio. He was given the essential oil treatment within five hours of the onset of symptoms. The vibrio ceased to exist after ten hours.

Case 3.—Lieutenant B., R.N., aged 26, also had symptoms similar to those of Case 1. His doctor at first treated him with opiates, but when he became worse the essential oil treatment was resorted to, and after eight doses at half-hour intervals the patient began "to feel himself again." Although both the surgeon commander and I had confirmed the diagnosis by microscope, when the patient was examined at the Naval Hospital, Hong-Kong, eleven hours later, no vibrios were found.

Case 4.—A woman, aged 26, with symptoms similar to the previous case and also marked tenderness over McBurney's point. The case was not notified to me until at least thirty hours after symptoms had appeared, and the patient was in a very weak condition and passing stools every minute or so. Essential oil treatment was immediately carried out, and within twenty-four hours the patient was convalescing.

Case 5.—A Chinese coolie, aged 48, had typical symptoms, as briefly described in Case 1; they began at 4 o'clock. Treatment by essential oils was commenced immediately, and at 9 o'clock the same evening the patient went home free from vibrios, and therefore a non-carrier.

Case 6.—This patient was a Customs officer, aged 32. His symptoms were similar to those of the other patients. Nine hours after treatment by essential oils no vibrios were to be found.

Case 7.—This patient, a commissioner, had the typical symptoms, but without any marked cramps; they commenced at 3.30 a.m. Microscopic examination showed numerous cholera vibrios to be present in the stools. Essential oil treatment was resorted to at once. At 6 a.m. the patient felt that he had taken a turn for the better; he was up the next morning by 10 o'clock. The stools were examined under the microscope and no vibrios found. At 2 p.m. the same day he resumed duty, although feeling rather weak.

Case 8.—In this patient, a nurse, the symptoms commenced with marked vomiting, then diarrhoea, which rapidly took on the appearance of rice-water stools. There were severe pains around the umbilicus, and the patient was so certain that she was dying that she did not want anyone to come near her and take risks. Essential oil treatment was given, and before sunrise the next morning she was well on the way to recovery.

This treatment could no doubt also be used in some kinds of intestinal toxaemia and in certain influenzal and rheumatic conditions. There seems to be no doubt that as a preventive and cure for cholera it is very efficient.

Memoranda:

MEDICAL, SURGICAL, OBSTETRICAL.

TRAUMA AND SARCOMA.

THE relation of trauma and malignant disease is a question which has always been debated in surgery, and cases clearly illustrating such a connexion are of considerable interest. It is now generally recognized that an important predisposing factor to carcinoma is the presence of chronic irritation, which may be a condition of mild, oft-repeated injury, either purely mechanical—as is often the case in epithelioma following the irritation of a jagged tooth—or mechanical together with a chemical factor, as is seen in mule-spinner's cancer of the scrotum.

Sarcoma, however, is often stated to follow upon a single injury, usually of a mild degree. Coley[1] has found a history of such trauma in 225 out of 970 cases of sarcoma, and the definite statement is made that a single injury may give rise to sarcoma of the breast, such a history having been obtained in nearly 10 per cent. of cases of this condition.

Boyd[2] states that sarcoma may arise after injury to bone, but the injury must not be of such severity as to give rise to a fracture. This apparently controverts a statement by Johnson and Lawrence[3] that sarcoma may arise at the site of a fracture; in the latter case, however, it is often impossible to decide if the tumour was caused by or gave rise to the fracture. Sarcomatous change in the callus has been given as the primary cause. Cerebral tumour (? sarcoma) is said[2] to have followed a slight head injury. It is also stated[3] that sarcoma rarely develops in a pre-existing benign tumour, but may occasionally occur in neurofibromatosis and endothelioma.

[1] Keen's *Surgery*, vol. 6.
[2] Boyd's *Surgical Pathology*, p. 160.
[3] Choyce's *System of Surgery*, vol. 1, p. 498.

These considerations render the following case of some interest in showing the development of sarcoma in a previously benign tumour following a definite injury.

A single woman, aged 40, a tailoress, came to me on May 11th, 1926, on account of a cystic swelling on the outer aspect of the left thigh; it resembled a sebaceous cyst. I removed it on July 5th under local anaesthesia and found that it was composed of a lobulated mass of fatty tissue; I took it to be a lipoma.

She again came to me on August 16th, and complained of the recurrence of "lumps" at the site of the soundly healed wound. There was a purplish cystic mass adherent to the skin, not sharply defined from the surrounding tissues and not adherent to the deeper structures. It measured 9 by 5 cm. Under general anaesthesia I excised the growth, removing the affected skin and going down to the muscles, which appeared to be free from any infiltration.

The specimen, which appeared to be made up of fatty tissue with two or three cystic spaces containing blood-stained fluid, was sent to Dr. H. A. Cookson, pathologist to the Royal Infirmary, who reported: "Section shows the presence of a marked sarcomatous change in a myxofibroma."

It was at this juncture that I was informed that the patient had had for "some years," at this site, a small lump which looked like a strawberry. She had noticed the gradual formation of the first cyst after a fall on December 14th, 1925, when she had bruised her left shoulder, side, and left thigh. On this occasion she had been under our care for the condition of the shoulder, but had not mentioned the injury to the thigh.

Present Condition.

The patient has had x rays (massive doses) applied to the site of the growth by Dr. Paige Arnold at the Royal Infirmary. The wound is now (November 11th, 1926) soundly healed except at its lower end, where there is some slight discharge, and some irritation of the surrounding skin. As yet there are no signs of recurrence, and she says that she is feeling in quite good health. She has now returned to her work.

Sunderland. H. B. L. LEVY.

HERPES ZOSTER AT FOURTEEN MONTHS.

THE following case is, I think, worthy of being placed on record.

A female child, aged 14 months, suffering from herpes zoster, was brought to the skin department of the Belfast Hospital for Sick Children on November 25th, 1926. The skin lesions were on the left leg, the nerves involved being the first, second, and third sacral. The areas affected were the sole of the foot and between the first and second toes, the posterior aspect of the middle third of the thigh, and the outer surface of the left labium majus. There was little or no disturbance in the general health of the child. The mother is healthy, and, to the best of her knowledge, the child has not come into contact with any cases of chicken-pox or "shingles."

The age of the patient is of special interest. Boix of Montevideo in 1917 recorded two cases—one in an infant 4 days old, and one in a child 4 months old.

IVAN H. MCCAW, M.B., B.Ch., B.A.O.Belf.,
Hon. Dermatologist, Belfast Hospital for Sick Children.

ACUTE YELLOW ATROPHY OF THE LIVER.

THE case here recorded seems to be of sufficient interest to merit publication.

An electrical engineer, aged 38, was admitted to St. John's Hospital, Lewisham, on March 8th, 1924, complaining of vague pain in the abdomen. He had been feeling unwell for four weeks, had been jaundiced and confined to bed for one week, and had vomited after food for three or four days. For the preceding three months he had imbibed alcohol freely.

He was deeply jaundiced and sleepy; he could be roused with difficulty, and it seemed too much of an effort for him to answer questions. He resented the approach of anyone near him, and his breath had a peculiar odour. There were no physical signs except that he resented pressure below the right costal margin. The bowels were constipated. Both urine and faeces contained bile. Temperature 97.7°, pulse 92, respirations 20. That night he became delirious and voided urine into the bed. On the following day the jaundice deepened and he became unconscious. His breathing was stertorous and his eyes were continually rolling from side to side. The area of liver dullness was diminished. Temperature 98°, pulse 108, respirations 26. He remained in this unconscious condition during the following day, and died in the evening.

A *post-mortem* examination was made and the only abnormal conditions were found in the liver and lung. The liver was shrunken and its capsule lax. It was of yellowish colour with red areas scattered throughout, especially along the anterior border. The pathologist described it as typical acute yellow atrophy of the liver. Unfortunately no microscope report could be obtained. The right lung showed an obsolete tuberculous lesion at its apex.

It was thought the condition might have been due to salvarsan or its derivatives, but there was no history of this, and at the necropsy there was no macroscopical evidence of syphilis.

I am indebted to Dr. Guy Neely for permission to publish this case, which is apparently very rare.

Swansea. T. J. EVANS, L.R.C.P.Lond.

SCIATICA: POTT'S DISEASE.

WHENEVER pains in the area of distribution of the sciatic nerve do not promptly disappear after removal of all septic teeth and septic tonsils, an x-ray search for tuberculous disease should promptly be made in the lower lumbar spines and lumbo-sacral and sacro-iliac joints—not omitting such an opportunity to take a radiograph of the hip.

At the moment (October 8th, 1926) I have two cases under treatment which had been diagnosed as sciatica. After considerable waste of time, radiological examination revealed in each marked lateral caries of the fifth lumbar vertebra; the Calmette test was positive. The patients were placed at absolute rest, out of doors, in a double "Liston" frame. The pains disappeared within a few weeks, and periodic radiographs demonstrate steady increase in calcification.

It is a remarkable coincidence that both patients are vigorous men about 40 years of age; both had various decayed teeth, including pus bags and socket absorption; both had led an outdoor "steady" camp life; both had served in the great war, and tuberculous disease is about the last thing that the previous existence or appearance of either would suggest. The fact, however, remains, and points the moral that it is not wise to view anything as neuralgia about face, joint, or spine unless radiological examination warrants such an assumption.

Buenos Aires. JOHN O'CONOR.

Reports of Societies.

CHANGES IN THE CLINICAL ASPECTS OF DISEASE.

AT the Medical Society of London on January 10th, Sir HUMPHRY ROLLESTON, Bart., delivered his presidential address (printed in full in this issue at pp. 87-91) on "Changes in the clinical aspects of disease." After the thanks of the society had been conveyed to him on the motion of Dr. E. M. CALLENDER, who said that while they were all aware of the changes which had taken place in disease it needed a master mind to bring them into focus as the President had done, a brief discussion took place.

Sir CHARLES BALLANCE, taking up the President's remarks with regard to small-pox, mentioned that in his own early days he was closely acquainted with Sir John Simon at St. Thomas's Hospital, and Simon once told him the interesting fact that when he was a boy there was only one criterion of beauty for an Englishwoman—she was considered fair if she had not had small-pox. The part played by vaccination in bringing about this striking change could not be over-emphasized. With regard to appendicitis, the speaker said that he was at one time clinical clerk to Dr. Charles Murchison, the greatest clinical teacher he had ever known. Under Murchison he saw many cases of peritonitis treated with mercury and antimony, and he recalled one clinical lecture given by Murchison on fatal cases in which pus was found in the neighbourhood of the caecum. He himself saw these cases not only in the ward but *post mortem*, because Murchison always took his class into the *post-mortem* room, and there he remembered distinctly Murchison pointing out ulcerations of the appendix. That must have been about 1878, yet at that time there was no suggestion of operation on the appendix. Suppurative appendicitis had indeed been described and illustrated as early as 1850. He had been interested also in what Sir Humphry Rolleston had said

about hydatid disease, and he remembered one physician of the old days at St. Thomas's who always kept in his pocket an ordinary pocket-knife, and when he got a case of swelling over the liver which he said was a hydatid cyst he used to make an incision through the skin with the pocket-knife. He also carried in his pocket a piece of copper wire, which he bent round into a hook, and this he put into the cyst to pull out the daughter cysts. The speaker also commented on the great changes which had taken place in the aspects of syphilis, and the entire disappearance, thanks to better treatment, of the horrible ulcerations formerly seen.

Sir WILLIAM HAMER rejoiced in the emphasis laid by the President on a conception which sometimes had been lost sight of—namely, that what was being dealt with in disease was not merely the germ or the human body, but the reaction between the two. So magnificent an expenditure of energy had been devoted to elucidating the wonderful subject of bacteriology that the fact had slipped out of sight that, after all, the disease was the reaction. Since his retirement he had been devoting his leisure to the study of epidemiology, and he had been interested to find that the writers of the eighteenth century were quite surprisingly clear on the point that it was this reaction which had to be considered, and even in the seventeenth century Sydenham had clearly in mind the root idea of modern immunology, that the exciting cause—that is, the germ—had to work upon the blood and humors, and that it was the reactions which accounted for the different clinical manifestations; and Sydenham's contemporary Willis was perhaps even more explicit on this subject.

Sir PERCY BASSETT-SMITH mentioned the change in character which had occurred during the last thirty years in Mediterranean fever. In the old days, when the wards were full of cases of this disease, it was characterized by acute fever, intense sweating, painful arthritis, and a good deal of neuritis. Nowadays the cases were quite different. One rarely found arthritis at all, and the type of fever generally was not so severe. In the cases described from South Africa, and in those also from Italy and the South of France, there seemed to be much more tendency to haemorrhagic complications and to slight meningeal symptoms. This change of type had perhaps coincided with a change in the infective carrier. In the Riviera the carriers now seemed to be, not goats as formerly, but sheep; in Italy and also in South Africa the carrier was now thought to be cattle. It seemed possible that the organism, by passing through certain animals which were not so likely to suffer from the disease as goats or human beings, had undergone a certain amount of change in virulence and in character, and so had produced a disease which was very different from that formerly seen.

Mr. ZACHARY COPE said that a physician or surgeon could almost be "dated" by his experience or lack of experience of certain diseases. One instance on the surgical side was the acute perforating gastric ulcers which were formerly very commonly found in chlorotic young women. Such cases were now seldom encountered—he himself had not seen one for fifteen years. Cases of glands in the neck were also seen much less commonly than formerly. One might almost date a surgeon if he was found to be familiar with ileal kinks as a disease. Occasionally the effects of treatment gave rise to new diseases, which again could be dated. One example was *x*-ray epithelioma. Presently a violet-ray epithelioma might be forthcoming, though he had not himself seen a case as yet.

Dr. H. A. DES VOEUX doubted the conclusion which the President had suggested with regard to the relationship between influenza and appendicitis. Influenza was certainly not a new disease. It was known four or five hundred years ago, and was recorded in medical literature under different names. The name "influenza" was given to it early in the eighteenth century by a London physician, his reason being that, as he said, it was a disease which flowed like a river from the king in his palace to the peasant in his cottage. Dr. Des Voeux thought that appendicitis also must be a good deal older than was generally supposed. When many of those present were young they came across a good many cases of acute peritonitis—a disease which had now died out owing, he supposed, to the prompt measures taken for the removal of dangerous appendixes and of gastric or duodenal ulcers. Appendicitis in milder forms was probably fairly common long before it was diagnosed as such. Patients came with acute painful indigestion, or sometimes with recurrent attacks of bilious vomiting and abdominal pain. These, he thought, were cases due to inflammation of the appendix, and they were strikingly common thirty or thirty-five years ago.

Dr. F. PARKES WEBER said that one of the difficulties in any discussion of this kind was the change of name of diseases. This applied, of course, to encephalitis lethargica, and to many other conditions. What was not usually noticed was that the same name was used at different periods for totally different diseases. Some time before the war a disease, characterized by redness and pain in the extremities, was described as epidemic—not very common, but still not rare—in Australia, and Dr. H. Smith gave it the unfortunate name of erythroderma. People immediately began to cast about for a name which would describe this disease in children, and erythromelalgia was hit upon, which was correctly descriptive, but unfortunately had been used previously by Weir Mitchell for the malady which he first described in 1872. There was another name, so to speak, on the market—"acrodynia"—meaning pain in the extremities, and this name was suggested and had apparently gained the day, for he noticed that it was accepted in Abt's *Textbook of Children's Diseases* in America, and also in the French medical journals. But this name had been used for an extraordinary epidemic disease which swept over Europe, especially France, a hundred years ago, and from which an enormous mass of people, chiefly old people, suffered. He could not think that this disease in children for which the name "acrodynia" seemed likely to come into general use could possibly be the same as the acrodynia which created such an impression in the early part of the last century.

ABDOMINAL TUBERCULOSIS.

AT a meeting of the Section of Surgery of the Royal Society of Medicine on January 5th, the President, Mr. V. WARREN LOW, in the chair, a discussion on abdominal tubercle was opened by Mr. H. W. CARSON.

Mr. Carson said that abdominal tubercle, as seen by the surgeon, was often very hard to diagnose, and the conditions found at operation might also lead to difficulties. Cases of abdominal tubercle in which he had operated during the last eight years comprised tuberculous peritonitis, enteritis, appendicitis (in one case), and ileo-caecal tuberculosis, while the majority of patients suffered from tuberculous mesenteric glands. Dealing first with tuberculous peritonitis, Mr. Carson described three varieties—ascitic, adhesive, and caseous—the latter being really a stage of mesenteric gland tuberculosis. The ascitic form, he said, might occur as an acute manifestation, and the adhesive form represented a further repair stage of the ascitic type. The scope of operative treatment was well illustrated in the case of the ascitic type, for these cases did well after simple laparotomy. The old theory to account for this ascribed the cure to admission of air and light, while a more recent view explained it on the grounds of an outpouring of a fluid rich in antibodies into the peritoneal cavity. The adhesive cases, on the other hand, did not benefit by laparotomy, which, indeed, was often dangerous, and did well if left alone, operation being reserved for cases with obstruction. Mr. Carson stated that tuberculous enteritis was a disease of middle age, and probably only occurred in cases where infected sputum was swallowed. He described some cases of ileo-caecal tuberculosis, all of the hyperplastic type, which he had treated by resection; no cases of the entero-peritoneal type had been met with in the period under review. The case of tuberculous appendicitis had been diagnosed by pathological examination after removal. Mr. Carson referred to a paper on tuberculosis

of the mesenteric glands read before the Medical Society of London in 1918. He said his views had not changed since that time; he still held that rise of temperature did not occur in uncomplicated cases of mesenteric tuberculous glands, and, dealing more particularly with a recent series of cases, he described the principal symptoms. Pain, especially on running about, was common, and vomiting might occur. The other causes of colicky pains of this nature in a child which had to be considered were colic from dietetic causes, a relapsing appendix, worms, and ureteric calculus. The complications which might arise from tuberculous mesenteric glands included intussusception in the non-caseating type and obstruction in the caseating type. In one case haematemesis had occurred, and in another melaena had been present with other symptoms of duodenal ulcer. In caseating glands complicated operations were sometimes necessary, especially if obstruction was present. Three patients in whom resection had to be performed had died out of 19 non-caseating cases which had required operation, 10 patients were quite well, but too many cases appeared to be not entirely satisfactory as regards health after operation. It had to be borne in mind, however, that cases of mesenteric tuberculous glands were serious. In summing up, Mr. Carson stated that he was seeing fewer cases of this disease now than in past years, and he believed that if the milk supply could be satisfactorily controlled the number could be still further reduced.

Mr. V. ZACHARY COPE said that in dealing with abdominal tubercle he proposed to exclude renal tuberculosis and psoas abscess and deal with the three main forms affecting the intestine, the peritoneum, and the glands. Tuberculous glands might be small and multiple, and might form a mass in the ileo-caecal region and simulate appendicitis. They also occurred in large fleshy varieties, forming small tumours, and secondary changes comprised caseation and calcification. Tuberculosis of the peritoneum occurred in an acute form sometimes simulating acute abdominal disease or as a miliary subacute form which might occur without any symptoms. Mr. Cope then proceeded to correlate symptoms with pathological conditions, pointing out that as a general rule deterioration of health was marked in all these cases. The small glands gave rise to colicky pains, while the large ones sometimes presented themselves as abdominal tumours. Calcified glands were generally diagnosed by *x*-ray examination. Of the intestinal varieties, hypertrophic caecal tuberculosis gave rise to the formation of a tumour, while intestinal obstruction might occur in this and other forms of intestinal tuberculosis. Tuberculous ulcers generally resulted in diarrhoea, while, if they perforated, faecal fistula might follow in some cases, acute peritonitis being set up in other instances. Of the peritoneal forms, acute tuberculosis presented all the appearances of acute peritonitis, while the chronic miliary form gave rise to ascites. Dealing finally with indications for surgical intervention Mr. Cope said that this consisted of letting out ascitic fluid, remedying obstruction, dealing with perforation, opening abscesses, and dealing with fleshy glands if these were causing symptoms. He added that it was difficult to know when to touch these glandular cases.

Dr. M. CASSIDY (continuing the discussion for the Section of Medicine) agreed that tuberculous enteritis was becoming less common, due, he believed, to the general decrease in all cases of tuberculosis and to the segregation of tuberculosis cases in special hospitals and departments. He then dealt with a series of 267 cases of tuberculous peritonitis treated at St. Thomas's Hospital during a recent ten years period. He thought there was no sharp line between the ascitic and the adhesive varieties, but he disagreed with Mr. Carson as to the latter being only a stage of repair. The prognosis in uncomplicated cases of tuberculous peritonitis appeared to be uniformly good, although it might run a long course. The symptomatology was rather variable. The disease might be latent and only discovered by radiologist or surgeon. Pain was very variable and might be absent, severe, or continuous. It was more common in adults with the plastic type. Diarrhoea and constipation might both occur. The diagnosis was often difficult, especially in cases with an acute onset within the first twenty-four hours of an attack. In adults more chronic cases were confused with abdominal carcinoma. Pyrexia was not conclusive as a sign, but very important was a peculiar rubber-like resistance of the abdomen wrongly described as doughy. Chronic non-tuberculous peritonitis might cause difficulty, and cirrhosis of the liver sometimes led to error. Dr. Cassidy remarked that the diagnosis between an ovarian cyst and tuberculous peritonitis was a traditional difficulty, but he had only once encountered it. Treatment of tuberculous peritonitis consisted in simple laparotomy followed by treatment on sanatorium lines. The speaker next dealt with tuberculous entero-colitis, basing his remarks on recent work by Brown and Sampson. In one form intestinal tuberculosis was associated with pain and diarrhoea, and was usually fatal. The other variety was hyperplastic ileo-caecal tuberculosis. Diagnosis was helped greatly by radiological evidence, particularly Stierlin's "filling defect."

The PRESIDENT said that even if "caseous peritonitis" occurred with abscesses bursting at the umbilicus, the mortality was surprisingly low. The ascitic variety of tuberculous peritonitis had an excellent prognosis, and diagnosis was not difficult even in the acute forms, since children seemed so well with their apparently serious condition. There was seldom any refilling of the abdomen after operation in these cases, and he believed that Sir Almroth Wright was responsible for the view that, following operation, a fluid of high bactericidal power exuded into the peritoneal cavity. The speaker thought that adhesive peritonitis was not a stage in repair, since cases began as this type, which was often very malignant and frequently fatal. He thought that the traditional difficulty between ascites and ovarian cyst dated from the time of Spencer Wells. He did not believe that tuberculous mesenteric glands were such a serious condition, since these glands were so commonly involved in children; the symptoms ascribed to the presence of these glands might be really due to complications. Attacks of sudden severe pain in such cases usually had a mechanical cause. He generally preferred to leave such glands alone at operation.

Mr. CECIL ROWNTREE stated that he had been converted to Mr. Carson's views on mesenteric gland tuberculosis, and there was experimental work to support them. Tuberculous mesenteric glands should be regarded as a separate category, while abdominal tubercle in general could be looked upon as complications of these glands. He thought that all these patients showed pyrexia during the early stage of invasion, following which they often appeared to get well, but were never robust. Surgeons then met these cases later on because of attacks of abdominal pain, which might be spontaneons or brought on by exercise. Such patients were mostly operated upon as cases of appendicitis, and they generally got better. It was suggested that the appendix was the source of infection in these cases. If glands gave rise to symptoms he thought they should be removed by dissection.

Dr. J. A. RYLE discussed the early diagnosis of mesenteric gland tuberculosis when this still gave rise to no physical signs and no severe pain, in the stage when the patient ought to get well without surgery. Such early stages might be recognized by loss of energy in a child, accompanied by evening pyrexia of 99° or 100°. The temperature must be carefully taken, and preferably per rectum. Stomach-ache of a mild degree also occurred, which was characteristically vaguely localized in both iliac fossae. Failure to increase in weight and height was also common, and a mild, chronic diarrhoea, with pale, unformed stools, was a frequent symptom. Food was not absorbed owing to obstruction to the lacteals. In old-standing cases in adults anaemia was an important sign which had often to be looked for carefully.

Mr. MORTIMER WOOLF inquired about the necessity for resection in ileo-caecal tuberculosis. He also asked if all the glands found were necessarily tuberculous, since with an inflamed appendix, for example, enlarged glands of an inflammatory type might be expected.

Mr. CARSON, in reply, stated that he had found so many cases with symptoms, but with only enlarged glands to

account for them, that it seemed that such symptoms were not those of complications. He thought that appendicular infection acted by lowering the resistance of the glands draining that region, and he agreed that the glands seen were probably not all tuberculous.

TRYPANOSOMIASIS IN MAN AND ANIMALS.

AT a joint meeting of the Sections of Comparative Medicine and Tropical Diseases and Parasitology of the Royal Society of Medicine on January 5th, with Sir D'ARCY POWER in the chair, a special discussion on trypanosomiasis in man and animals was opened by Dr. W. H. ANDREWS.

Dr. Andrews drew attention to the importance of the subject to medical practitioners and veterinary surgeons. The classification of the various species of trypanosomes found in man and animals was difficult, but he was pleased to see that it was becoming much simplified in the more recent textbooks. It was dangerous to define new species on the basis of biological differences, and virulence and cross-immunity tests were not reliable for this purpose. The effects of artificial transmission tended to make a strain monomorphic and in many cases to increase its virulence. This mechanical transmission, as distinct from surgical transmission, should be the subject of field experiments. In Zululand, where he personally had had most experience, several species of trypanosomes occurred. *T. brucei* had not been found since its discovery; it was a monomorphic form, and the species there were polymorphic. In that country were also found *T. vivax* and *T. congolense*, the latter being the main form in cattle. The virulence of different strains was affected by many factors, such as the species of host, the breed, the age, and so on; and Dr. Andrews thought that the effect of the mammalian host on the parasite had not been sufficiently studied. A factor of importance in prophylaxis was the domestic animals which might often form a reservoir which could not be neglected. He personally was in favour of the control of wild game, as the effects of the rinderpest outbreaks had caused a marked diminution of the disease. The results of chemiotherapy were conflicting and there seemed to be two aims—namely, attempting to sterilize the animal's blood, or, alternatively, to check the first onset and allow the body to fight the parasite itself and so become more or less immune; this advantage was absent in the first method.

Dr. P. MANSON-BAHR confined his remarks to a discussion of the treatment of the disease in man. He said that there were two features to be observed when any new drug was introduced into tropical medicine. First, its action on artificially infected animals did not necessarily correspond with its effect on man; and, secondly, there was great variety in the reactions of individual patients to the same drug, man responding in a much less mechanical manner than did the ordinary laboratory animal. Dr. Manson-Bahr then discussed the actions of two recently introduced drugs. "Germanin," or "Bayer 205," or "Fourneau 309," as it was variously called, was a white flocculent powder of aniline origin which might be administered in various ways, but was generally given intravenously. A single injection caused disappearance of all the parasites from the blood stream in about eighteen hours, although there was a remarkable proliferation just immediately before their disappearance. The blood appeared to be sterilized almost immediately, but there was evidence that a Bayer 205-fast strain might be evolved, and relapses sometimes occurred after 5 grams had been given; twice this amount was generally allowed for a complete cure. This drug was a definite kidney irritant, and irritation might persist for several weeks after treatment had ceased. It did not affect the meningeal reaction, and therefore patients in the second stage of the disease were not permanently cured; they almost invariably relapsed. Intrathecal injections were dangerous and death might result. Dr. Manson-Bahr's own impression was that Bayer 205 was the drug of election in early haemic infections, especially in those instances in which the parasites had become "fast" to arsenic or antimony, and he quoted two of his own cases to support this statement. The second drug was the arsenical compound tryparsamide, which also was usually given intravenously. There was convincing evidence that the drug exerted a profound influence on the meningeal reaction in *T. gambiense* cases, and that it was the drug of election in the second and third stages of the disease, in which Bayer 205 had no effect; he quoted two cases to illustrate this point. In conclusion he expressed great hopes for the future treatment of the disease; at present the most effective treatment was a combination of the two drugs, or alternating treatment to avoid "fastness," since each seemed to be the antithesis of the other. Natives would not remain in hospital for prolonged treatment, and it was only by the use of some such rapid method that a large proportion of them could be benefited.

Dr. J. GORDON THOMSON drew attention to some aspects in the biology of the trypanosomes, and asked whether the polymorphic strains in man were the same as those in animals. He found that they tended to become monomorphic through long mechanical transmission. Thus in rats which had been injected with *T. brucei*, *rhodesiense*, or *gambiense* the organism became monomorphic and resembled *T. cruzi* or *equiperdum*. Sudden changes of hosts tended to transform these monomorphic forms back to polymorphic, and in rats arsenical drugs might have the same effect. He had found that *T. gambiense* was often very difficult to inoculate into rats; sometimes six months would elapse before the parasites would be found in the blood, but subinoculations tended to enhance the virulence until it would become fixed for that animal, although sometimes the virulence decreased. He found that, although tryparsamide appeared to cure the host, the organisms could still be found in the cerebro-spinal fluid; the host had become tolerant to strains otherwise lethal.

Dr. NEAME exhibited the eye of a dog with a keratitis due to trypanosomes. It most closely resembled the keratitis seen in dogs with distemper and the interstitial keratitis of syphilis in man.

Colonel F. HARVEY stated that in restudying some of Bruce's original slides he found that *T. congolense*, *vivax*, and *brucei* were present, and that the latter was polymorphic. Now the strains of *T. brucei* at home were monomorphic, and this had been found only once by him in a dog in Nyasaland. With difficulty flies had been infected with it, and, contrary to expectation, the form which resulted from the cyclical infection was still monomorphic. He suggested that this was the form originally sent home by Bruce. If the polymorphic variety had been sent home in a dog, the animal would have died long before reaching England, as the polymorphic *brucei* caused a very acute disease in dogs and killed them in about ten days. Another species, *T. simiae*, caused a very acute disease in monkeys and pigs, but a chronic one in goats. If, however, it was subinoculated from goats to monkeys, the disease produced was now chronic, although cyclical transmission through the *Glossina* was acute.

ASTHMA IN CHILDREN.

AT a meeting of the Brighton and Sussex Medico-Chirurgical Society on January 6th, Dr. ROBERT HUTCHISON (London) read a paper on asthma in childhood.

Dr. Hutchison said that the disease at this period of life might assume one of several forms: (1) true spasmodic asthma which was chiefly met with in later childhood; (2) the hay-fever type often diagnosed as a simple "cold"; (3) bronchial asthma—namely, bronchitis with a spasmodic element; (4) the bronchitic type. The last was peculiar to children, being chiefly met with during infancy, and its asthmatic nature was often overlooked. It was to be distinguished from ordinary bronchitis by its sudden onset and subsidence, by the fact that dyspnœa preceded the appearance of physical signs, by the comparative absence of fever, and by the presence of eosinophilia. So-called thymic asthma, or the para-asthma of some American writers, must be distinguished from ordinary asthma. The asthmatic paroxysm might be brought about either through the respiratory centre or by direct action on the bronchi. The respiratory centre might be acted upon psychologically, as by fright, excitement, or auto-suggestion; reflexly, from

the nasopharynx and stomach; and by the blood. The substance in the blood which might act either upon the respiratory centre or directly upon the air passages was a foreign protein to which the patient was hypersensitive. Hypersensitiveness might be either inborn or acquired, and it might vary from time to time. Such sensitiveness to food proteins was usually inborn, that to inhaled substances acquired. About 50 per cent. of all asthmatic children showed hypersensitiveness as demonstrated by skin tests, but in only a minority of these could the specific cause of the asthma be determined. The noxious protein might be ingested in the form of some food; inhaled as pollen or dust; or bacterial, from a chronic focus of infection. The methods of detecting the different forms of hypersensitiveness were then described. Passing to the treatment of the asthmatic tendency, it was pointed out that success lay in recognizing that asthma was not a disease of the respiratory system only. It was important also to break the "habit" of asthma. The general management of the child and the effect of climate and diet were then discussed. Great benefit was often obtained from the prolonged use of a mixture of potassium iodide, arsenic, and belladonna or stramonium. Sedatives such as chloral helped to prevent threatened attacks. Operations on the nose and throat and the use of vaccines were then considered. In the hypersensitive cases general desensitization of the patient was the ideal, but was difficult to effect; various methods of attempting it were described. As regards the prognosis of asthma in childhood, Dr. Hutchison's experience had on the whole been favourable. In a large proportion of cases the tendency appeared to be outgrown.

RESUSCITATION AFTER SYSTEMIC DEATH.

AT a meeting of the London Association of the Medical Women's Federation on December 14th, 1926, the President, Miss ELIZABETH BOLTON, in the chair, Dr. HARRINGTON SAINSBURY read a paper on the problem of resuscitation after systemic death.

Dr. Sainsbury said that systemic death, while putting an end to the corporate life of the body, viewed as a collection of associated organs and tissues, did not terminate somatic life—namely, the life of the body viewed as a collection of dissociated organs and tissues. At the moment of systemic death these organs and tissues retained more or less individual life and had their several rates of dying, though the tenure of life was not of long duration even for the most hardy. Since the blood served as a carrier of elements indispensable to the tissues, its coagulation point was a crucial factor in the determination of the possibility of resuscitation. While the blood remained fluid systemic life might be regarded as capable of resuscitation, given the persistence of a sufficiency of somatic life in the tissues generally and in the heart specially. As a practical problem the question of resuscitation would scarcely arise in the case of death at the natural term of life; here the vital powers had for a long while been manifestly ebbing, in spite of the use of such stimulants as diet and medicinal measures. Neither would it arise in the case of long drawn out and exhausting diseases, such as tuberculosis and cancer, where all the evidence indicated that there could only be a temporary rally. The likelihood, however, of a recovery of the powers of the mind and body, which, though brief, might yet suffice to permit of some important act, had to be considered, but such cases would be rare. On the other hand, the problem became eminently practical in proportion as it appeared that the inherent powers of the tissues, severally, were unexhausted and that the systemic death present was rather of the nature of a suspended animation which had arisen more or less abruptly in the heart or the lungs. In such cases, the somatic vitalities being still adequate, there was no reason why life should not proceed to its normal term if the heart and the respiratory apparatus could be restarted. At the threshold of life this problem arose in the case of the stillborn infant, in whom the indications pointed either to an arrested heart or unstarted breathing; in the average course of life this same problem recurred repeatedly as the result of accident, acute disease, during an operation, or even during the administration of an anaesthetic before the operation had begun. Dr. Sainsbury pointed out that the great disparity between the forces engaged in the respiratory and in the circulatory functions made resuscitation of the latter system a much harder task. For though the first breaths taken after birth had to overcome a very considerable inertia of the respiratory apparatus, respiration once established, the muscular effort required in normal breathing was no more than that needed to move the volume of tidal air in and out of the chest. In the absence of obstruction to the air passages, restarting of arrested respiratory motion was comparable to the slight touch which started the pendulum of a wound-up clock. On the other hand, when the circulation of the blood had failed a force had to be supplied to meet a great resistance—namely, a pressure corresponding in man to approximately 150 mm. of mercury in the aorta. Fortunately it was not necessary that the full momentum of the circulation should be generated all at once. The elasticity of the arterial system and the mechanism of the aortic valve permitted the summation of small efforts and gave the necessary time for recovery. Dr. Sainsbury said that the period during which the blood remained fluid and the heart muscle retained its contractility could not be given precisely in minutes, but must vary with the individual; in practice the longest recorded time between apparent systemic death and resuscitation would stand as a working precedent. Certain cardiologists had doubted the susceptibility of the heart to direct stimulation, but in his opinion this attitude of scepticism ran counter to most definite evidence. As to the most powerful means of revival, Dr. Carl Bodon of Budapest had collected from the literature the records of ninety cases in which the various recognized stimulants had been tried, and from the study of the results placed adrenaline first. Dr. Sainsbury gave details of the method whereby 1 c.cm. of a 1 in 1,000 solution of this drug could be injected into the cavity of the right ventricle, this dose being suitable for a middle-aged man. An alternative reliable method of stimulation was cardiac massage. Dr. Sainsbury held that the use of adrenaline should come first, on the following grounds. (1) The simplicity of the procedure and its rapid applicability, in these cases the sooner the stimulants acted the better; (2) when effective, the response would appear to be more prompt; (3) the comparatively slight risk involved; (4) the general disturbance, a negligible quantity. Dr. Sainsbury concluded his address with a discussion on the ethics of resuscitation, and asked if it was always right for a doctor to rekindle life in a patient who might not be grateful for his recall. His duty was to cure, or, failing this, to prolong life, upon terms; apart from this, he must try to make life more endurable; but was it his duty to thrust life upon an unwilling recipient? Medicine existed to relieve, not to inflict, burdens. These objections would not arise in the case of stillbirths, where the duty to suscitate (not resuscitate) was unquestionable, and in the event of sudden, unanticipated, unprepared-for death the case for resuscitation must be overwhelmingly strong. Therefore, in every hospital, in every nursing home, and in the emergency equipment of every medical practitioner, the apparatus for intracardiac injection should be kept in readiness. Adrenaline should not be kept reserved until life had departed, but in every case in which the heart was ceasing to respond to hypodermic or intravenous injections, intracardiac injections should be tried in order to forestall death if possible.

Lady BRISCOE, from her work on experimental animals, endorsed what Dr. Sainsbury had said about the case of restarting respiratory movement and the difficulty of restarting the heart. She had never found cardiac massage of much value. In cats accidentally killed from an overdose of chloroform she had noticed that the diaphragm was not excitable after death, though other muscles remained excitable. She thought that deaths from chloroform might possibly be due to direct poisoning of the respiratory muscles.

Dr. LETITIA FAIRFIELD suggested that it was dangerous to speculate about the ethics of resuscitation; a newly born infant might be resuscitated to a life of many troubles, yet no one would question the doctor's duty.

Reviews.

LAW AND TRADITION OF MEDICAL PRACTICE.

MEDICAL students and practitioners cannot complain that they are left in ignorance of the legal relations of the duties and responsibilities involved in the practice of medicine. Teachers have lectured and authors have written freely on this topic. But the exposition has been presented mainly, if not entirely, from the medical platform, and it is from this source, we fancy, that instruction has reached the student of law as well as the student of medicine. A not unwelcome departure from precedent is to find the subject discussed as the lawyers see it. Hence we are strongly disposed to receive with gratitude Messrs. SANDERSON and RAYNER'S book entitled *An Introduction to the Law and Tradition of Medical Practice*.[1] That the measure of our gratitude is modified on perusal of the volume we admit. None the less there are advantages in listening to our legal instructors, even though on individual points we believe them to be in error. A learned judge recently proposed that lawyers should lecture to doctors and doctors to lawyers; perhaps to ensure adequate instruction—for the lecturer.

Quite naturally our legal authors warn us that it is incumbent on every citizen to know the law; that ignorance of the law is no effective reply to a charge of unlawful conduct; that, lawyers excepted, members of the medical profession have to know more law than any other class of the community; and that beyond these general claims some fifty special statutes demand our particular attention. The burden is a formidable one, and Messrs. Sanderson and Rayner attempt to lighten it, not by reciting the provisions of individual statutes, but by an exposition of the purposes to which the law is directed and by an application of legal principles to existing circumstances and to actual facts. Medical practitioners are not untrained in their legal obligations, but they know these for the most part as empirical demands; and for the rough practical claims of life this knowledge is not insufficient. The present volume rests on appeal rather than on command. The provisions of the law are argued as matters of principle and as historical developments, and the enterprise makes some very readable and highly interesting pages. To this recognition of the merits of the book we must add an entirely grateful word in appreciation of the enlightened and generous interpretation which the authors bring to the motives and standards of the medical profession. In this respect we could not desire more considerate and understanding judges.

When, however, we proceed to test the book in detail the result is by no means wholly satisfactory, and we are the more bound to notice certain defects seeing that the present volume is presented as a mere preliminary sketch or summary, and is to be followed by a larger work intended to include a full discussion of the rights and duties of medical practitioners. If errors exist it were well to try to check them before they are placed in a more impressive setting. We will quote some examples. On p. 30 we are told that medical men "must not employ unqualified dispensers or chemists"; on p. 22 the Central Midwives Board is quoted as one of the authorities responsible for the education and discipline of the medical profession; p. 26 says that "it is considered advertisement to write signed articles in lay papers," and that the General Medical Council makes exception in this respect "in cases of eminent members of the profession"; in a footnote to p. 44 a list of "defence associations" includes two organizations that do not undertake this function; and when discussing the responsibilities of medical consultation, p. 23 alleges that it is "contrary to etiquette" to inform the patient that there is disagreement when this exists. We could extend this list, but the instances quoted are sufficient to show that the book, though animated by a sincere desire to understand the medical point of view; must suffer a critical revision before it can be trusted as an authority on medical tradition and practice.

Nor are the authors wholly successful in dealing with such delicate questions as unqualified practice and the medical attitude towards the relations between insanity and crime and between professional secrecy and the witness-box, though in discussing the last mentioned the motives directing the medical claim receive a degree of recognition not frequent in the legal forum.

As might be expected from their legal training the authors have considerable capacity for lucid statement, but what, we wonder, is the exact meaning of the sentence "Where an unqualified man establishes for himself such a reputation as to build up a practice, he is not unreasonably interfered with by law"? And must we accept the implication that "reputation" and "practice" attached to an unqualified person give him a status in the eye of the law different from that credited to another unqualified person who cannot boast these achievements?

In the preface "public health" and "forensic medicine" are excluded from consideration. Accept this restriction, and it yet remains strange that a book professing the present title should be free from all definition of the duties falling upon doctors under the laws relating to lunacy, notification of infectious diseases, notification of births, cremation, the status of the *Pharmacopœia*, and the use of "dangerous drugs." Guidance on these points is much more needed by practitioners than is advice on book-keeping and the issuing of accounts, and to get such guidance we would willingly have sacrificed even the learned and interesting discussion on the validity of contracts and the definition of torts.

Academically it may be an open question whether lawyers or doctors are the better equipped to write books on the legal responsibilities of medical practice. To judge from our bookshelves the doctors hold the field, and the present volume is hardly likely to disturb their peaceable possession.

We repeat that the book is an engaging one. It has a sincere motive and is eminently readable. Where it presents legal propositions we must respect its authority though even here we are not quite free from doubts. But on a number of points of medical tradition and practice it is not complete and is not well informed, and these defects seriously qualify its value.

FINLAYSON'S CLINICAL MANUAL.

WE welcome the fourth edition of the *Clinical Manual for the Study of Medical Cases*,[2] originally written by the late Dr. James Finlayson of Glasgow, who died in 1906, and so no doubt will many medical men who, now approaching the age when retirement is not far distant, were brought up on its predecessors. The last edition was published thirty-five years ago (reviewed in the JOURNAL, 1891, ii 1153), and the present work, edited by Professors C. H. BROWNING, E. P. CATHCART, and LEONARD FINDLAY, has of necessity been revised throughout, and in places almost entirely rewritten, by twenty men closely associated with Glasgow at the present time or, in the case of Professor J. Shaw Dunn of Manchester, Dr. Maitland Ramsay and Professor Adam Patrick of St. Andrews, in the recent past. There is, however, one exception to the thorough revision—namely, in the late Sir William Gairdner's classical article on the physiognomy of disease, to which the only, at any rate only obvious, addition is a page on basal metabolism. Otherwise the substance of the work has now been so greatly changed that the editors might well have brought out a manual of this kind under their own names, especially after an interval so long as to be perhaps unique among current medical textbooks, had they not dutifully been anxious to perpetuate the essentially clinical character so distinctive of Dr. Finlayson's *Manual*, and to confine the description of tests and methods to those which can be carried out in the wards or in the attached clinical laboratories.

[2] *Finlayson's Clinical Manual for the Study of Medical Cases.* Fourth edition. Edited by Carl H. Browning, M.D., E. P. Cathcart, M.D., F.R.S., and Leonard Findlay, M.D., D.Sc.; revised and augmented throughout by various contributors. London: G. Bell and Sons, Ltd. 1926. (Post 8vo, pp. xvi + 815; 4 plates (3 coloured), 143 figures. 18s.)

This is not a manual of laboratory diagnosis, but a guide the worker while in the wards, and at the present time, when much in the investigation of clinical cases may be delegated to whole-time workers in a somewhat distant laboratory, this distinction is not without its value as an example to ambitious writers of similarly entitled works as to what the clinical clerk and student really want. As the editors rightly point out in their brief preface, there is a real danger that the present multiplicity of chemical, bacteriological, and serological tests may induce the student to rely on them so much that ordinary physical examination may be neglected and become a lost art; as two out of the three editors are laboratory workers, this protest must be reckoned unbiased and therefore of all the greater weight. The methods recommended to be used have been chosen with care and there is no reason to fear that they have been unduly curtailed; there are illustrations and explanations of phlebograms and electro-cardiograms, descriptions of test meals and the examination of the faeces, and an account of the method of performing Rijmans van den Bergh's test. The significance of the Wassermann reaction, but not the method of carrying out the test itself, is given; whereas the methods of performing the Schick and Dick tests are mentioned. The twenty-one chapters in this new edition retain, embodied in present-day knowledge, the practical nature and philosophic spirit characteristic of Dr. Finlayson's original volume.

The only entirely new article is that on disease of the glands of internal secretion by Professor E. P. Cathcart, who gives a broad sketch of the various changes which may suggest endocrine disorder; he points out that operative removal of an endocrine gland being sudden differs from disease, which, being slow in its progress, allows the body time to make a whole series of protective measures. He pays a warm tribute to the Toronto physiologists in the discovery and production of insulin. The article had evidently gone to press before Dr. C. R. Harington's recent work on thyroxine appeared. The chapter on affections of the blood and lymphoid tissues has been practically rewritten by Professor Carl Browning and Dr. Ernest M. Dunlop, who have added a successful coloured plate of the blood cells. The section on the eye, which Dr. Finlayson made rather a feature in his original editions, has been wisely entrusted to Dr. A. Maitland Ramsay, now Director of the St. Andrews (James Mackenzie) Institute for Clinical Research, and those on the ear and the upper respiratory and alimentary tracts are safe in the hands of Dr. Albert A. Gray and Dr. A. Brown Kelly respectively.

In conclusion, it may be said that this new edition admirably justifies its aims and should prove as popular as its ancestors.

THE STRUCTURE OF COLLOIDS.

PROFESSOR WOLFGANG PAULI has published in a small volume two lectures he delivered on proteins and colloids,[1] the one to an assembly of medical men and the other to chemical students. The author is one of the leading authorities on colloidal chemistry, and states very clearly his belief that "all colloidal and protein reactions can be accounted for by electrostatic exchanges, provided that regard is paid to the relation between chemical configuration and the spatial arrangements and intensities of electric fields."

This view is based on the modern theories regarding the structure of molecules, and consists essentially in an extension of the laws, which are recognized by physical chemists to govern the hydration of inorganic salts, to account for the behaviour of substances when aggregated in particles of colloidal dimensions. This conception leads the author to disagree with many of the theories of Loeb, who sought to explain the behaviour of proteins chiefly by the laws governing the Donnan membrane equilibrium. The subject is of great interest to all workers in the biological sciences, for protoplasm is a colloidal substance, and there is no chance of understanding anything of the fundamental laws governing the behaviour of living matter until the laws of colloidal chemistry are placed on a secure basis. The questions that arise are of exceptional difficulty, but Professor Pauli has succeeded in enunciating a few basic conceptions in terms as simple as the subject permits.

THOMSON AND MILES'S "SURGERY."

THREE volumes of the seventh edition of THOMSON and MILES'S *Manual of Surgery*[1] have been issued. Their appearance, as Mr. Miles says, has been delayed by the untimely death of Professor Alexis Thomson. The book has long occupied a unique position in English surgical literature. In its style and teaching it is characteristic of the sound and thorough work of the Edinburgh school. It is perhaps a book rather for aspirants to the Fellowship than for those who seek to pass qualifying examinations; but to the latter it is a valuable book of reference, for it can be said that there is very little of importance in surgery—academic, theoretical, or practical—which cannot be found in its pages. The effort at compression has perhaps been carried a little far, and the southern student might wish for a more detailed classification.

The work is clearly and concisely written, the most modern views are expounded, and the illustrations are abundant, though the publishers might perhaps have taken greater pains to bring out more clearly some of the *x*-ray photographs. Each volume is of convenient size and has its own index. The first volume, which deals with general surgery, contains chapters devoted to general bacteriology, inflammation, suppuration, ulceration, gangrene, wounds, and the repair of tissues; tubercle, syphilis, and tumours each have a chapter, and next come others on injuries, on the blood vessels, on the lymphatic system, and on the nerves and the skin, on tendons and muscles, on bursae, and on the diseases of bone and joints. The second volume contains ten chapters on the extremities, in which the various fractures, dislocations, and deformities are described and their treatment discussed. Eight chapters follow—on the scalp, skull and brain, and on the spinal cord. The third volume deals with the thorax and abdomen, and includes a discussion of the clinical aspects of abdominal and pelvic conditions peculiar to women. In this volume the information is particularly concise. On the subject of enteroptosis the Edinburgh school appears to deprecate the majority of slinging or fixation operations of the bowel, some of which have survived a rather extensive trial. The spleen usually receives scant attention in surgical textbooks, but here a word on splenectomy for purpura haemorrhagica might have been included. The treatment of haemorrhoids by injection of carbolic acid is not mentioned. It is curious that reproductions of cholecystograms seem so far not to have found their way into textbooks.

We can thoroughly recommend these volumes as forming a valuable work of reference in surgery, and congratulate the author on the successful way in which he has prepared the seventh edition.

[1] *Manual of Surgery.* By the late Alexis Thomson, M.D., F.R.C.S.Ed. and Eng., and Alexander Miles, M.D., LL.D., F.R.C.S.Ed. Vol. I, General Surgery, Vol. II, Extremities—Head—Neck; Vol. III, Thorax—Abdomen. Seventh edition. Oxford Medical Publications. London: Milford, Oxford University Press. 1926. (Cr. 8vo: Vol. I, pp. xiv + 565, 169 figures; Vol. II, pp. xvi + 663, 297 figures; Vol. III, pp. xii + 567, 169 figures. 12s. 6d. net each volume.)

CAVERNOUS SINUS THROMBOSIS.

DR. WELLS P. EAGLETON of Newark, New Jersey, has presented, in a volume entitled *Cavernous Sinus Thrombophlebitis and Allied Septic and Traumatic Lesions of the Basal Venous Sinuses*,[1] a study of twenty-five cases of cavernous sinus thrombophlebitis he has himself observed. Naturally allied conditions such as thrombophlebitis of the jugular bulb must come into the discussion, but the main thesis is indicated in the title, and the experience of the author, if not unique, is certainly unusually large. Dr. Eagleton is already well known from his book on brain abscess and other publications relating to the intracranial complications of middle-ear and nasal infections, so that this new work will at once command attention and respect.

The twenty-five cases are very elaborately reported with full commentaries, and there is in fact so much detail that

[1] *Cavernous Sinus Thrombophlebitis and Allied Septic and Traumatic Lesions of the Basal Venous Sinuses.* By Wells P. Eagleton, M.D. New York: The Macmillan Company. 1926. (Post 8vo, pp. xxiii + 195; illustrated. 4.50 dollars.)

the reading is rather hard, but as a scientific contribution there is nothing lacking in them. There is also a full analysis of the literature on the subject with bibliography.

The cases are sufficiently numerous for a rational classification into six types depending upon the route by which the sinus is originally infected. Dr. Eagleton points out that even in a case of aural origin it may be necessary to drain an abscess at the apex of the orbit as well as to open the sinus. He also advocates, in certain cases, ligature of the common or internal carotid to give rest to the infected venous sinus, a proceeding for which he assigns good reasons. It may be strictly logical but does not appear to have been very successful, and its drastic nature is likely to cause some surprise, even if it does not excite hostile criticism. Enough, however, has been said to show that Dr. Eagleton has made a careful study of this terrible complication and has made a notable contribution to our knowledge of intravenous infections.

NOTES ON BOOKS.

DR. F. J. BROWNE, formerly of Edinburgh, where he worked with the late Dr. J. W. Ballantyne—to whose foresight he pays a becoming tribute—has produced a useful small book entitled *Advice to the Expectant Mother on the Care of Her Health*.[6] In the first chapter popular prejudices are answered by reciting the benefits to be obtained by the mother from regular visits to the doctor during pregnancy, and their eventual good effects on the child. The remaining chapters are devoted to normal pregnancy, hygiene of pregnancy, common disorders and their treatment, preparation for confinement, and hints on breast-feeding. There are no frightening references to possible complications, and the little book can be given to any expectant mother; by following the instructions given she will derive great benefit.

The Heart,[7] by Dr. A. G. GIBSON, is another of the useful Oxford Medical Handbooks, and in a small volume of one hundred pages the author has given a very fair summary of the present state of knowledge of cardio-vascular disease. The first half of the book is concerned with such subjects as general considerations on the circulation, the clinical examination of the patient, the normal heart and circulation, and instrumental methods of examination; in these chapters nothing seems to be omitted that is important from the clinical point of view. The same may be said of the subsequent chapters dealing with diseases and disorders and with the principles of prognosis and treatment. Students and practitioners, to whom the volume is addressed, will find it well worthy of careful reading.

MRS. EVELYN FULLER, who is honorary secretary of the Society for the Provision of Birth Control Clinics, has written a pamphlet entitled *On the Management of a Birth Control Centre*,[8] founded on four years' experience at the Walworth Women's Welfare Centre, of which she is the superintendent. This centre was established over four years ago by the Malthusian League, and later taken over by the Society for the Provision of Birth Control Clinics. The account of the equipment necessary for such a clinic is concise yet complete. The choice of premises, arrangement of lighting and plumbing, necessary furniture, and the most useful case records are described and illustrated. The short description of the personnel, which must necessarily include a medical practitioner and at least one medical woman, and the general management of the clinic is good. Opinion is divided on the necessity for birth control clinics, and at the present time voluntary effort must be entirely responsible for their management and control. To those who contemplate undertaking the provision of such a centre this pamphlet provides all the information required.

The forty-third annual issue of the *Year-Book of the Scientific and Learned Societies of Great Britain and Ireland*[9] retains the general arrangement of contents which has been found satisfactory in the past; the size remains about the same. In the preface reference is made to the retarding influence on science and learning generally of the prolonged dispute in the mining industry, but the reports in the *Year-Book* show that work is being steadily carried on. The societies are classified in fourteen groups: general science; astronomy, mathematics, and physics; chemistry and photography; geography, geology, and mineralogy; biology, including microscopy and anthropology; economic science and statistics; mechanical science and architecture; naval and military science; agriculture and horticulture; law; literature, history, and music; psychology; archaeology; and medicine. An index is provided. The section on the British Medical Association occupies three pages, and includes a list of papers communicated at the Annual Meeting at Nottingham last July.

The *Proceedings of the International Congress of Obstetrics and Gynaecology* in celebration of the centenary of the Coombe Lying-in Hospital, Dublin, in September, 1926, have now been issued, and copies may be obtained from the manager of the *Irish Journal of Medical Science* at Parkgate Printing Works, Dublin, price 5s. 6d. post free. The volume is illustrated with numerous plates, some coloured, and a preface is contributed by Dr. L. Cassidy, Master of the Coombe Lying-in Hospital.

BRITISH EMPIRE CANCER CAMPAIGN.

A QUARTERLY meeting of the Grand Council of the British Empire Cancer Campaign was held on January 11th, under the chairmanship of Sir CHARLES GORDON-WATSON. The grant of £600 for the whole-time services of a medical officer to the London Association of Medical Women's Federation, which has been using some of the radium belonging to the Campaign, was renewed for a further period of one year, and a grant of £500 was made to Mr. F. C. Pybus for expenses in connexion with certain cancer research work to be carried on at Newcastle-on-Tyne. Reports were received from the representatives of the Cancer Campaign who have been visiting the principal American and Continental cancer research laboratories. It was stated that research work in the leading American laboratories was of a very varied character and was being liberally supported in the United States. The lines of research were very similar to those in Europe, but several new methods of technique were being employed. Appreciation had been expressed in the United States of the value of the *Cancer Review* published by the British Empire Cancer Campaign as an admirable connecting link between the research workers of the two countries.

A confidential report was received from the deputation of the Campaign which visited Liverpool to investigate the lead treatment conducted by Professor Blair Bell.[1] On the recommendation of the Scientific Advisory Committee a grant not exceeding £1,000 was made to St. Bartholomew's Hospital for the purpose of making new investigations of problems arising from the Liverpool work. This grant will come up for reconsideration from year to year for the next five years, and the investigations will be under the control of a scientific committee at St. Bartholomew's Hospital consisting of Sir Thomas Horder, Sir Charles Gordon-Watson, Mr. W. D. Harmer, Mr. J. E. H. Roberts, Dr. M. Donaldson, Dr. G. Graham, Professor F. L. Hopwood, Mr. J. B. Hume, and Dr. R. G. Canti. The Grand Council expressed the hope that the Liverpool medical research organization, which is now responsible for all arrangements in connexion with the investigations of Professor Blair Bell and his colleagues, will associate itself with the coming appeal of the British Empire Cancer Campaign in Lancashire and Cheshire, which has already been joined by Manchester University. It is announced that the funds subscribed in connexion with this appeal will be mainly devoted to the Liverpool organization, and to Manchester University for medical research at the Christie Hospital.

Among those elected to membership of the Grand Council was Sir D'Arcy Power, who had been nominated as a representative of the Imperial Cancer Research Fund. Sir William Willcox was elected a member of the preliminary inquiry committee of the Campaign.

British Medical Journal.

SATURDAY, JANUARY 15TH, 1927.

CHANGES OF TYPES OF DISEASE.

WRITERS of "best sellers" or of paradoxical drama may criticize us, or offer kindly suggestions for the reform of medical training and treatment in the columns of the less responsible lay journals; but so long as the acknowledged leaders in medicine show such a depth of knowledge and breadth of outlook as has been displayed by Sir Humphry Rolleston, the profession will scarcely vouchsafe more than a tolerant smile to the spectacle of fussy impertinence which the lay would-be reformer offers to the public in his highly remunerated articles.

We congratulate the Medical Society on its choice of a President, and Sir Humphry Rolleston on his surely unique record of the successive Presidencies of the Royal Society of Medicine, the Royal College of Physicians, and the Medical Society of London. In taking the changes in the clinical aspects of disease for the subject of his address to the latter society, which is printed in full at page 87, we think that he made a wise choice, for it is of great importance that every now and then we should be reminded of many things which find no place in textbooks, and of the changes which take place around us so gradually that in the stress of daily work we hardly notice them. The speaker did not profess to have any startling new facts or theories to offer to his hearers, nor did he inculcate any methods of treatment, but by looking back on the history of acute, and especially of infective disease, and aided by the perspective which time alone confers, he was able to provide much food for thought and for reflections which may greatly benefit future practice.

Less than fifty years ago, for example, articular gout or podagra, chlorosis, hyperpyrexial articular rheumatism, and malignant scarlet fever seemed to be as much in the fixed and immutable order of things as the movements of the planets, so that no one would have ventured to predict that before the fourth decade of the twentieth century such conditions would have become rare, without our knowing why. We may, indeed, flatter ourselves that improvements in our habits of life may have led to the mitigation or abolition of these scourges, but we have no more valid evidence in favour of this explanation than we have, on the other hand, for the view that those diseases, such as appendicitis, which have increased in prevalence or severity are due to a change or changes of habits and surroundings of a less benignant kind. That old enemy of health, influenza, had been well-nigh forgotten when it revisited us in fury in 1889 after forty years' absence, and in its subsequent outbreaks it has been characterized by such widely different symptoms as to arouse doubts of the identity of the infection in one year with that in another. This reflection reminds us of the fallacy of regarding diseases as fixed morbid entities, for the diseased state of the patient depends upon other important factors besides the invading poison. The discovery of certain micro-organisms and the assignment to them of the causative role in certain specific diseases seemed to justify the assumption that all other infectious maladies were due to similar causes, and that when these causes became known we should be able to assign the maladies in question each to its own microbe as an entity, and to treat it successfully as soon as an efficient microbicide was found. Greater experience has shown that such a view is based on very imperfect knowledge. The manifestations of disease depend for their nature upon more factors than the identity of the micro-organism detected in each case. The seed is no more important than the soil, which, being a living animal organism, may and does vary in its suitability to the growth of the invader. It has long been known —and the knowledge has been used again and again in prophylaxis—that the virulence of the infective organism may be modified, and it had been suspected long before it was established that apparently spontaneous modifications may occur. It has been held that thus diseases which seem to be new, such as encephalitis lethargica, may originate. Moreover, the whole story is not told when a specific organism has been found. It may be accompanied by one of another and less specific kind whose presence and activities profoundly affect the symptoms and the result of the illness. For instance, it is plausibly argued that scarlet fever runs a mild or a malignant course according to the absence or presence of a secondary organism.

Sir Humphry Rolleston referred to many more epidemiological and endemical puzzles. Why has appendicitis become, as it undoubtedly has, so much more common of late years since the days when Parkinson of Hoxton first described it? Why was urinary calculus so much more common in Norfolk than in the rest of England, and why has East Anglia lost its bad eminence in this respect? We have prided ourselves perhaps too much on having stamped out malaria in this country by drainage and other hygienic measures, just as surely as the United States abolished it from the Panama Canal zone. Yet the fens, and the deadly Kentish marshes so well described by Dickens in *Great Expectations*, are little if at all better drained than they were when it was death, or at least dreadful illness, which lurked in them ready to attack the "unsalted" stranger. There are plenty of anopheline mosquitos here, ready to spread the infection, and since the war thousands of men have returned to this country having the malarial parasites in their blood. Yet happily we are practically free from malaria. Our ignorance concerning this and other important pathological problems should not make us despair, but should inspirit our pathologists and urge them on to the many triumphs which are surely awaiting them and their successors in the years to come.

THE NEW EDUCATION PROPOSALS.

IT is not difficult to sustain the thesis that education and health are not two subjects, but merely different aspects of the same subject. This is abundantly clear if health be regarded, as it should be, not as the mere absence of disease, but as the complete development of body and mind—indeed, of the whole personality—to the full extent of whatever powers they possess. The medical profession and health administrators are concerned mainly with one aspect of this development, and the teaching profession and education administrators with another, but the work of all these must not only be intimately associated in its day-to-day performance, but should also involve a broad acquaintance of each with the aims, problems, and difficulties of the others. Such an understanding will not be without its influence upon the practical solution of such difficulties. The school medical service should

form an integral part of the public health service and administration, but that is not to claim that it can be successfully carried on without the hearty co-operation of the teacher and the education officer. The effective conduct of physical exercises and teaching of personal and domestic hygiene in the schools cannot fail to be of great service to the public health, but they are likely to be the more effective if conducted or given by a competent master or mistress in the ordinary course of the school curriculum in general accordance with a syllabus drawn up by an experienced medical authority. Psychological tests applied by the doctor and teacher are valuable, not merely in the diagnosis of mental deficiency, but as aids to the classification and advancement of individual pupils. A disregard by either of the experience and skill of the other would be foolish. Any hiatus in medical supervision such as that which now commonly occurs between the age of 14, when the child leaves school, and the age of 16, when he becomes an insured person, is peculiarly unfortunate, and may be remedied more effectively by educational than by medical reorganization. Practical illustrations of this intimate co-relationship could be multiplied, but these are sufficient to show that such new and far-reaching proposals as those contained in the Report of the Consultative Committee to the Board of Education on "The Education of the Adolescent" must be of profound interest to the medical profession, not only in their broader aspects, but also in many of their details.

On another page we publish an article expounding and discussing these proposals. Broadly, they are proposals for (1) the abolition of the present distinction between elementary, secondary, and technical education, and the regrading of school education into (*a*) primary, up to 11 or 12 years of age, and (*b*) post-primary, after that age; (2) the lengthening of the school life of the normal child or adolescent up to 15 years by compulsion after due notice, and beyond that age by attraction or persuasion; (3) the provision of a variety of school and curriculum in the post-primary stage to meet the varied needs of different pupils, establishing in the main two types of school—the "grammar school," with a curriculum predominantly literary or scientific, and the "modern school," with a more practical or vocational, but not purely utilitarian, bias in its later years; (4) the institution of new areas, with an effective unification of educational administration in each. The exact nature and bearing of each of these proposals is considered in some detail in the article printed at page 114, and, in the light of the comments there made, it is to be hoped that many members of the medical profession will make themselves acquainted with the relevant portions of the report itself. Whatever controversy may arise on certain points, it can hardly be doubted that the general suggestions of the report will commend themselves to all concerned with public health and education.

One matter should receive special notice—that relating to the areas of local administration and unification within them. The almost exact similarity between the proposals of the Consultative Committee as regards education and those of the British Medical Association as regards public health is very welcome. It is perhaps not remarkable, since the Association itself pointed out in its Memorandum of Evidence for the Royal Commission on Local Government that it was probable that the suggestions there made "would be equally suitable for the best provision and administration of education in its various forms." We should like to call attention also to one of the many valuable pronouncements in the appendix on suggestions on teaching. The Committee says: "We regard it as especially important that instruction in elementary physiology and hygiene, developing out of the lessons in elementary biology, should be given to all boys and girls in modern schools and senior classes." Why not in other secondary schools also?

Another passage, paying tribute to the late Dr. J. G. Adami, will be read with particular appreciation by members of the medical profession. It forms the last paragraph of the preface to the report. "We cannot end without recording our sense of the loss which the Committee has sustained by the death of Dr. Adami. He had been a member for the last six years; he had taken a leading part in the preparation of our last report; and he was a member of the subcommittee in which the present report was gradually drafted. He had won the affection as well as the respect of his fellow members; and he contributed generously both to their deliberations and to the shaping of their conclusions."

THE CINEMATOGRAPH.

TWENTY million persons are computed to visit a cinematograph theatre every week in the British Isles. The effect of witnessing these silent performances is of interest from many points of view, and Miss Barry has presented an interesting judgement on the mental effects.[1] She considers that the habit of watching films develops a special kind of alertness which renders the habitué in some degree a better student of human nature; he receives suggestions, and observes manners and gestures that are not apparent to the infrequent visitor. The mental effect she judges to be the very antithesis of witnessing a dramatic performance. At the theatres there is gained a new experience, one that gives temporary vigour. The cinematograph soothes and drugs, so that the watchers come out like sleepers awakened. "The theatre is a tonic, the cinema a sedative. . . . And that is why, after the feverish activity of a day of modern life, the screen calls to us more strongly than the footlights." Investigations have been made from time to time upon the physical effects of these displays. What influence, if any, has the cinematograph upon the eyes? That so many go to the pictures and so few complain is evidence that not much harm is done. But some do complain. They suffer so severely that they can never be persuaded to repeat the experience.

Apparently the first paper on the subject was published in this JOURNAL in 1917, when Mr. Bishop Harman gave an account of observations of the effects produced upon children who frequently visit these displays.[2] Such ill effects as were observed were, he considered, due to glare, flicker, rapidity of motion, bad position, concentration of attention, and duration of exhibition. Many of these defects have been reduced or even eliminated by the improvement of the film, the machine, and the places wherein the shows are given. He concluded that the shows caused no harm to most of the children provided visits were not too frequent. In a later paper dealing with the children in the myopic classes of the London area[3] he recommended that "attendance of children of myope classes at cinematograph displays should be discouraged. Short-sighted children suffer readily from eye fatigue, which may cause more lasting injurious effects. All forms of music should be encouraged,

[1] *Let's Go to the Pictures.* By Iris Barry. Chatto and Windus. 7s. 6d.
[2] Harman, N. Bishop: BRITISH MEDICAL JOURNAL, February 17th, 1917, p. 219.
[3] Idem, ibid., February 2nd, 1924, p. 204.

particularly playing and singing by ear." Dr. J. Alexander Wilson made a contribution on the subject in 1920.[4] Seeking to find the cause of eye fatigue arising out of film exhibitions, he considered that "Absence of natural colour in the photograph renders identification of the objects more difficult and increases the necessity for fixation and attention." An investigation was made by a joint committee of the London County Council in 1919 into the causes of eye-strain in cinemas; its report furnished much valuable data for the improvement of film production and exhibition, and particularly in regard to the position of the observer in relation to the screen.

Quite recently a new investigation has been set on foot by the Section of Ophthalmology of the American Medical Association, and a preliminary report has been issued.[5] Investigations were made upon 150 persons—university students and senior and junior high school children. The subjects of the observations were first examined as to their visual acuity under conditions that were held to eliminate error, then exposed to film exhibitions for one and a half hours, and immediately retested as to visual acuity. A further set of tests were made on the same lines; but for exposure to the cinematograph the reading of current magazines in a good light for forty-five minutes was substituted. "More fatigue," it is reported, "is evident after forty-five minutes of reading current magazines than by viewing either a black-and-white or a coloured motion picture for one and a half hours, if one uses the visual acuity as a criterion for fatigue. Coloured films are not more fatiguing than black-and-white, but seemed to cause less fatigue. Those who suffer eye-strain from motion pictures are those who are unable to accomplish other ocular work without fatigue." Much of the weight of these findings will depend upon the test for visual acuity employed, and upon the answer to the question whether visual acuity is the proper criterion. In the discussion that followed the presentation of the report criticism turned about two points. The first was whether distance vision of a screen which did not require accommodation was comparable to reading which did need accommodation; the second was that the fatigue experienced at cinema shows was "principally a retinal fatigue, largely associated with the fact that there is a dark interval about half as long as the light interval, interrupting the light stimulus fifteen or sixteen times a second."

The matter is one that is worthy of extended observations, particularly as to the truth of the suggestion that those who suffer from attendance at these exhibitions are those who are unable to accomplish other ocular work without fatigue.

SERUM DIAGNOSIS OF CANCER.

WHILE it is recognized that there is no specific reaction in cancer, it is held reasonable to assume, *on a priori* grounds, that tumour cells invading the tissues must act to some extent like parasites and induce defensive reactions in the organism. Numerous methods have been employed during the last twenty years in the hope of establishing a serological diagnosis of cancer—namely, complement fixation, the precipitin reaction, passive anaphylaxis, hetero- and iso-lysins of the red cells, the cutaneous reaction, carcino-lysins, the antitryptic reaction, the reducing power of the serum, the epiphanine reaction of Weichardt, surface tension reactions, Fischer's reaction of the protein equilibrium of the serum, electrophoresis, or the precipitation observed at the positive pole, variations in the serum content in sugar, cholesterin, amino-acids, fatty acids, and phosphoric acid, in the alkalinity of the serum, and in the quantity and quality of its proteins. The results have been disappointing as contributions to the diagnosis of cancer, although many of the tests seem to indicate that a tissue reaction does actually occur as the result of cancerous invasion, and will repay investigation. One of the tests which have attracted most attention is that devised by Botelho. In its original form it gave a positive result in 48 per cent. of cases of cancer; a closer examination of the conditions of the experiment and the adoption of a modification securing greater uniformity has raised the positive results to 90.4 per cent. Negative results in non-cancerous serums remained practically the same with both methods—namely, about 85.5 per cent. The principle of the test is based on the fact that, with an acidified solution of iodine, cancerous serums, in contrast with the majority of non-cancerous serums, give a permanent precipitate in the presence of definite quantities of the reagent. Botelho subsequently found that if physiological salt solution were added to the serum the results varied with the degree of dilution; with the same serum a positive result was observed in dilute serum and a negative result in concentrated serum. By taking the precaution of using serums with a definite protein content (78 to 80 per cent.) he succeeded in obtaining the more satisfactory results above mentioned. Dr. Tedesco-Polack has recently introduced a modification in the technique, which is said to yield results both more definite and more constant than that used by Botelho himself. Uniformity in the protein concentration is secured with the aid of the refractometer, and Dr. Tedesco-Polack has given full directions for carrying out each step of the test in a pamphlet[1] recently published. Observations were made on 200 cases in the Hôtel-Dieu, Paris; these are fully reported, and the general conclusion drawn is that, when it is remembered that the serological diagnoses were carried out before operation and before a histological diagnosis was made, and often in cases where the clinical diagnosis was doubtful, "it would appear, in view of the high percentage of correct forecasts, that Botelho's reaction, as practised with a preliminary correction of the refractive index of the serum, is of practical value in the diagnosis of cancer; the reaction, moreover, is easy in manipulation and interpretation."

FLOUR SUBSTITUTES IN FRANCE.

MANY people in France have been concerned, from the public health point of view, at the introduction, as the result of the financial difficulties in France, of various substitutes for wheaten flour in the manufacture of bread. It appears that in 1922 a committee advised the Ministry of Agriculture to postpone compulsory use of substitutes for flour, but that in rye-producing districts the mixture of this grain in the proportion of 10 per cent. should be allowed. In December of that year, however, the Ministry issued an order making the addition of 10 per cent. of rye, barley, maize, or rice compulsory. The difficulties in carrying out this order were so great that with the first good harvest it was revoked. This year, however, it has been revived, and buckwheat, manioc or tapioca, and what are called "D grains," have been added to the list of substitutes. The Académie de Médecine recently appointed a committee to investigate the subject, and at a meeting on November 9th Dr. Lapicque presented its report. It found that the use of the substitutes did not endanger the public health; but thought it expedient to carry its inquiries further, and to investigate the effects of the

substitutes on the manufacture of bread. Maize, rice, and tapioca cannot, when used alone, be made into bread, since they lack the gluten necessary to agglomerate the starch grains. Added to wheat flour these grains are so much inert powder; and as the cultivation of wheat has aimed at an increased production of starch, the gluten of the wheat is now insufficient to combine the wheat and the substitute into good bread. Barley and rye can be made into bread; but barley bread is not pleasant, and rye bread, so dark as to be called black, does not rise well, and has a flavour more distinctive than agreeable. Buckwheat, though it cannot actually be made into bread, has an effect similar to rye when mixed with wheat flour in the proportion of 10 per cent. D grains are not really substitutes, since they are "offals" extracted from wheat in the production of flour. Their introduction into flour has led to difficulties in obtaining uniformity in the appearance of the bread. According to the committee, the skill of the baker is upset, commercial difficulties arise from the Frenchman's desire for white bread, and indigestion is produced by an unpalatable or unexpected flavour or appearance in the loaf. Uniformity is considered desirable on social and on physiological grounds. This cannot be obtained when several different substitutes are used, either alone or in combination. Control is impossible, since it can only be conducted through microscopical examination —a very difficult method for obtaining quantitative results. From the economic point of view the committee has not discovered any advantage in the use of substitutes; all of them must be imported; and although rice comes from a French colony the piastre of Indo-China is as independent of the franc as the pound sterling or the dollar. The only substitute of importance, in the opinion of the committee, is rye, because in certain districts in France it can be grown better than wheat; but in suitable districts the use of buckwheat might be allowed. For the rest a flour from which less offal has been extracted is productive of economy; and this economy could be increased if millers were not left continually in hopes of a return to white flour. The extraction of flour, says the committee, should be fixed for a period, say, of five years. At the request of the Colonial Union of France the discussion of the report has been postponed.

WHAT IS THE FATIGUE SYNDROME?

THE last quarterly number of the *Journal of Neurology and Psychopathology*[1] contains a paper on fatigue by Dr. R. D. Gillespie, Henderson Research Scholar in Mental Diseases. He begins by saying that there is no satisfactory definition of fatigue. It is possible, however, that his difficulty arises from the application to a special pathological condition of a word that is used in common parlance. To the ordinary man fatigue is a result of sustained labour or exertion. It is physiological, and involves nothing abnormal. The condition with which Dr. Gillespie is dealing appears to be a syndrome to which some people give the name neurasthenia, and of which one symptom, at all events, is "irritable weakness." The use of the term in this connexion appears to be confusing; and the confusion is not diminished by the sense in which it is used by the Industrial Fatigue Research Board. Consequently we find all the definitions of fatigue mentioned by Dr. Gillespie unsatisfactory, whether that to which he objects, "a diminished capacity for work"; or the evasive formula of Janet, "Fatigue is the behaviour of a man at rest: the sensation of fatigue is the desire for that behaviour"; or the definition accepted by Gillespie for clinical purposes: "A person is fatigued when he is capable of less general activity than is usual with him, or when he is capable of less activity than would be expected from his general mental and physical equipment; and when the diminution of activity is accompanied by a sensation of fatigue, or of exhaustion, or of weakness." Would it not be better to invent a new word if neurasthenia is insufficient, and leave fatigue to the layman? According to Dr. Gillespie the cause of the "fatigue syndrome" may be sought in five directions, and first in the constitution of some people who have an inborn defect of function. The second direction is auto-intoxication, but in this case he thinks it equally possible to regard the fatigue and the gastro-intestinal disturbances as having a common origin. Thirdly, overwork has been suggested as a cause; but experimental production of prolonged irritable weakness by work alone is lacking. This statement seems to be in itself sufficient to condemn the technical use of the word "fatigue." Fourthly, emotional causes have been suspected, so that for Dejerine "the real cause of fatigue lies in the emotional equipment." In favour of this theory there is some evidence, both clinical and experimental. Lastly, there are theories which Dr. Gillespie calls "psycho-analytic," according to which neurasthenia is the result of excessive masturbation. The symptoms of the fatigue syndrome are "brain-fag," poor memory, lack of concentration, irritability of temper, increased reflexes, poor sleep, anorexia, and aches and pains. He divides his cases into five groups according to the symptomatic importance of the fatigue of which the patients complained. He considers that the principal place in treatment must be assigned to psychotherapy, but that graded exercises will increase exercise tolerance and vital capacity, hydrotherapy will improve vasomotor tone, and the administration of phosphates will prolong the working power of muscle.

PARA-THOR-MONE.

THE success of Collip in devising a method for preparing a stable preparation of the active principle of the parathyroid gland has at last provided a sound basis for the investigation of the clinical value of this hormone. Until quite recently opinions regarding the experimental and clinical actions of parathyroid extracts were remarkable chiefly for their discordance. The work of Collip provided an explanation, for he showed that the parathyroid contained an active principle of great potency, but that most, if not all, of the principle was lost by the usual methods of preparation. He developed a technique by means of which this elusive active principle could be obtained as a stable preparation, and it is now being prepared on a commercial scale by Messrs. Eli Lilly and Co., under the authority of the University of Alberta. Collip devised a method of biological standardization of the active principle, and the clinical unit is one hundredth of the quantity required to cause an increase of 5 mg. per 100 c.cm. in the calcium of the blood serum of a dog weighing 20 kilograms. The preparation as issued contains 20 units per cubic centimetre; it can be given subcutaneously, intramuscularly, or intravenously. The human dose ranges from 10 to 30 units a day. The drug produces a definite and powerful physiological action, and has been found to be a true specific for the tetania parathyreopriva. It has also been found of value in idiopathic tetany, infantile tetany, and sprue. It has been tried in a number of other conditions, and it is probable that it will ultimately be found to be of great clinical value, for recent research has shown that the blood calcium is unduly low in a great number of diseases. Those who desire to employ this preparation must remember, however, that, like all drugs which produce a definite physiological effect, para-thormone must be used with care and discretion. Collip found that dogs would tolerate a large single dose, but that injec-

tions of even very small amounts repeated at intervals of a few hours invariably proved fatal if the injections were continued. The first symptom of an overdose was vomiting. In clinical cases as much as 100 units of para-thor-mone have been given in twenty-four hours without ill effects, but such doses are unnecessarily large, and could not be repeated without danger. Collip's work has aroused much interest in the medical profession in this country, and limited quantities of his preparation have already been tested here, both experimentally and clinically; it is satisfactory to learn that the drug will now be available for general therapeutic use. The agents in this country are Messrs. Allen and Hanburys, Ltd.

ACETYL-ARSAN IN SYPHILIS.

ACETYL-ARSAN is best known in this country as stovarsol. It was introduced into medical practice by M. Fourneau, and is No. 190 in the series of organic arsenicals prepared by him. The full title of the drug is oxy-acetyl-amino-phenyl-arsenate. Ehrlich commenced his long series of researches on antisyphilitic remedies with a study of the pentavalent arsenical compounds. He prepared acetyl-arsan in an impure form, and thought it to be unduly toxic. Fourneau, however, obtained the drug in a pure form, and arrived at the conclusion that it is a powerful antisyphilitic of very low toxicity. Ehrlich found that pentavalent arsenicals were less potent than trivalent arsenicals, and devoted his attention to the latter in the hope of obtaining a drug of which a single dose would produce a complete cure. In recent years, however, increasing attention has been paid to the pentavalent arsenicals. The new American drug tryparsamide is, for example, a member of this class. The characteristics of stovarsol are that it is absorbed rapidly, is of low toxicity, and is excreted rapidly in the urine. It is stated that it never causes optic neuritis, a danger which led to the abandonment of atoxyl, which was the first pentavalent arsenical to be used extensively in trypanosomiasis. Laurent[1] has employed acetyl-arsan extensively for more than three years, and reports very favourably on its action as an antisyphilitic. He found the drug particularly useful in the treatment of congenital syphilis in infants, because it could be injected hypodermically without producing irritation. Levaditi states that the drug is more active if given by mouth than when injected, and that it is of value in amoebic dysentery and yaws as well as in syphilis. The determination of the exact value of an antisyphilitic remedy is, of course, a problem which requires much work and a long period of time over which to test the drug. The clinical reports, however, are to the effect that acetyl-arsan has a remarkably low toxicity, and that it has a strong antisyphilitic action. The latter action is shown by its effect both on the clinical symptoms and on the Wassermann reaction.

STUDY OF MEDICAL HISTORY.

IN announcing lately that the Annual Meeting of the British Medical Association, to be held at Edinburgh next July, would include a Section devoted to the history of medicine, we mentioned that the University of Edinburgh was the first medical school in Great Britain to recognize the importance of this study by establishing a lectureship in it. This was done eighteen years ago, and appropriately enough the president of the new Section and the lecturer at Edinburgh are one and the same person—Dr. John D. Comrie. In an appreciative editorial comment on this announcement the *Journal of the American Medical Association* of December 4th, 1926, states that a few American medical schools have now regularly established courses in medical history, and that the Johns Hopkins University Medical School has just established a professorship in it, conferring the first appointment on Dr. William H. Welch, whose services to this branch of study, as well as to bacteriology and pathology, are almost as well known to our readers as they are in the United States. Professor Welch, it may be added, is one of the twenty eminent corresponding members of the Historical Section of the Royal Society of Medicine. Commenting on the matter generally our contemporary writes: "The mark of the cultured man is a knowledge of the foundation and processes by which his art and his science reached their prestige. Unfortunately, too few physicians care to give the time or the interest necessary for even a moderate acquaintanceship with medical beginnings." If we may judge from the appreciation shown by readers of very varied tastes for the "Nova et Vetera" column of the BRITISH MEDICAL JOURNAL, and from other signs of increasing attention, we should say that the profession of Great Britain takes a keener and deeper interest to-day than ever before in the historical side of medicine. Apart from any other consideration, an occasional glance at the past helps to keep the present in perspective, and to point the way for future advances.

LISTER CENTENARY: LONDON CELEBRATION.

THE centenary of the birth of Lord Lister falls on April 5th, 1927, and a committee has been formed to organize a celebration in London. At the suggestion of the Royal College of Physicians of London, the Royal College of Surgeons of England, and the Royal Society of Medicine, the initiative was taken by the Royal Society, which is acting as a co-ordinating centre. The executive committee comprises representatives of the universities, learned societies, and medical bodies of the country, and, as recorded in the SUPPLEMENT of January 1st, the Council of the British Medical Association has nominated as its representative the President of the Association, Mr. R. G. Hogarth. Invitations to send delegates have been addressed also to various medical institutions in the Dominions and abroad. The celebrations will take place on Wednesday and Thursday, April 6th and 7th. They will include a reception of delegates and the delivery of short addresses by some of them, a commemorative service in Westminster Abbey, a reception at the Royal College of Surgeons, a conversazione at the house of the Royal Society, a dinner with the Merchant Taylors Company in its hall, and the delivery of discourses on Lister as physiologist, pathologist, and surgeon. The details of the programme are still under consideration, and we hope to give further particulars in a later issue. We have already published a preliminary note on the Lister celebration in Edinburgh, which will be held next July in order to coincide with the Annual Meeting of the British Medical Association.

X-RAY CINEMATOGRAPHY.

THE practicability of obtaining on a cinematograph film rapid serial skiagrams of the moving organs of the body and of the movements of the joints in health and disease was demonstrated by Dr. Russell J. Reynolds at a meeting of the Röntgen Society on January 11th. The films which he put through the projector, as was only to be expected, left much to be desired from the point of view of what the photographer would call "pluckiness," and something also from that of sequence, and the results were a prophecy rather than a fulfilment. The subject is still in the experimental stage, but what remains to be done to bring the work to the pitch of efficiency required in practice is chiefly certain optical improvements and the provision of photographic material of greater sensitivity. Dr. Reynolds has been engaged in this work for more than five years, and with the spirit of the pioneer he has been undaunted by frequent disappointments. There are two

methods by which moving x-ray pictures may be obtained. One is by the direct action of the x rays on a moving film after the rays have passed through the subject under examination. This seems the most obvious method, but it would be extremely costly and difficult to manipulate, if not altogether impracticable. The method Dr. Reynolds has preferred consists in taking a series of photographs of the shadow cast on a suitable fluorescent screen. These photographs are obtained by means of a cinematograph camera fitted with the necessary adaptations for the purpose. One of the principal difficulties has been to obtain sufficient light from the screen to produce an impression on the film, and as the light emitted from the screen is ordinarily blue, a very real problem is presented. Again, it is necessary to protect the camera with its unexposed film from the action of the rays, and this has involved the interposition of a sheet of lead glass between the fluorescent screen and the lens. The subject under examination has also to be protected. To reduce exposures to the minimum the x-ray tube is excited only for the interval of time required to permit of exposure, and Dr. Reynolds has worked out an ingenious method of synchronizing the opening and closing of the camera shutter with the switching off and on of the high-tension current. Dr. Reynolds was fortunate enough to secure the co-operation of the Kodak firm in obtaining a specially sensitive film and also a specially prepared fluorescent screen, fully 30 per cent. more brilliant than the French calcium tungstate screen which he had up to that point been using. With these improvements he was able to get quite passable impressions of the thorax of a boy with exposures of a quarter of a second for each picture, and the image of the thorax could be seen even with an exposure of only one-eighth of a second. To ensure the smooth movement of the camera mechanism he installed a small motor, and when this device was brought into play, in conjunction with the latest film and screen obtainable, he was able to get a satisfactory serial skiagram of the hand, showing the skeleton, with exposures of one-eighth of a second. This, together with the thorax picture, which showed the outline of the heart, was exhibited at the meeting. Professor E. A. Owen, of University College, North Wales, who assisted Dr. Reynolds in some of the earlier work, stated that he considered Dr. Reynolds had made a really valuable contribution to medical radiology. The need was for still more rapid x-ray films and greater brilliancy of illumination of the intensifying screen under x-ray action. One improvement which both Professor Owen and Dr. Reynolds foreshadowed was the use of a quartz right-angled prism to reflect the light from the screen at right angles, and so keep the camera out of the direct path of the rays, with consequent elimination of the lead glass protection. Although Dr. Reynolds projected many feet of film, he pointed out that in practice it would be necessary to take only a very few pictures—just sufficient in most cases to give one cycle of movement, which could, of course, be repeated any number of times on the positive film from the negative without having to subject the patient to prolonged radiation.

RARITY OF MALIGNANT MELANOMAS IN NEGROES.

IT is an old observation that malignant melanotic tumours occur in the anal region of horses; most commonly, according to Sir John Bland-Sutton, the affected animal is grey, but it may be white, and occasionally it is black. But very little reference is made in the extensive literature on melanomas to their racial incidence, and it is therefore interesting to hear from Dr. J. T. Bauer[1] that they have seldom been observed in negroes and deeply pigmented orientals. Melanomas are so striking that their existence is a matter of common knowledge; they cannot be said to be common tumours, and no doubt the difficulty of recognizing them in dark-skinned individuals may help to account for the rarity of their reported incidence. At any rate, this last and commonplace explanation must be taken into consideration before seriously regarding their rarity in negroes as a corollary to their reputed frequency in grey and white horses. Dr. Bauer has collected eighteen examples of malignant melanomas in negroes; in three the eye was affected, in the others the skin; he devotes his attention to the latter. Except for one which arose on the forehead, the cutaneous melanomas occurred on relatively unpigmented parts of the body, eleven being on the feet. Trauma appears to be the most important factor, and may precede the recognition of the growth by several years; this possibility, it is stated, should be considered whenever the nail-bed is injured and an indolent ulcer follows. From histological examination of two malignant melanomas —one of the thumb, the other of the big toe—in negroes, Dr. Bauer concludes that the pigment-containing cells were derived from connective tissue, and that the tumours were melanosarcomas. He does not offer any explanation for the relative rarity of malignant melanomas in negroes, and contents himself with saying that probably a number of undetermined factors are responsible.

THE EPIDEMIC OF INFLUENZA.

THE epidemic of influenza, which it is now recognized is prevailing in various parts of Northern Europe, seems to be of a mild type, though the customary stories of households stricken down almost simultaneously so that it has been difficult to maintain domestic service, are numerous. It has been stated that it is more prevalent in towns than in the country districts, but this does not seem to be true of this country. In Spain, according to a bulletin issued by the Health Section of the League of Nations, an epidemic was prevailing as early as the beginning of December, and in Switzerland it began about December 10th in the cantons of Berne, Basel, and Geneva; it is now prevalent in Zürich and Soleure, where schools have been closed. In Denmark it began in the third week of December. An epidemic had not been recognized in Germany down to January 8th, but the number of hospital admissions in Berlin has been increasing. The *Times* correspondent reported recently that there were 1,000 cases at Cologne and as many as 3,000 at Stuttgart, that the unofficial estimate for the Rhineland was 8,000 cases, and for Baden over 40,000. In Holland it is reported that since Christmas the number of absences for sickness among the staff of the public services is from 10 to 20 per cent., and two or three times as high as in January, 1926. From France the reports to hand refer only to Paris, and it is stated that of the 139 deaths from influenza in that city most were attributed to bronchopneumonia. The epidemic seems to be of the respiratory type in Belgium, and, so far as our information goes, in this country also.

AN AUSTRALASIAN COLLEGE OF SURGEONS.

A PLAN is on foot to establish an Australasian College of Surgeons. Preliminary meetings of surgeons were held some time ago in each Australian State, and two delegates from each and two from New Zealand attended a meeting held in Sydney last August. At this meeting it was agreed that it was advisable to form a College of Surgeons of Australasia, and forty foundation members were nominated. They were asked to take steps to formulate a constitution, and to place their scheme before those surgeons who attend the Australasian Medical Congress which is to be held under the auspices of the British Medical Association at Dunedin, New Zealand, early next month. It is expected that a final decision will then be reached.

INFANTILE PARALYSIS.

THE BROADSTAIRS OUTBREAK IN 1926.

We are indebted to Dr. A. M. Watts, M.O.H. East Kent (No. 1) United District, for the following extracts from his report on the recent outbreak of acute poliomyelitis in Broadstairs and St. Peters.

The urban district is situated at the north-east corner of Kent, between the boroughs of Margate and Ramsgate, placed on the chalk cliffs jutting out into the North Sea and facing the south-east, with a coast-line of nearly four miles. There are two and a half miles of promenades, and the foreshore provides several stretches of firm sands, which are swept daily by the sea. The population found by the census of 1921 was 15,471.

Owing to its reputation as a healthy seaside resort there are many private boarding schools and day schools in the district, the population of these being about 1,150 children. The total number of private schools is about twenty-six. There are also some thirteen convalescent homes, with accommodation for 900 persons, mainly children, and also holiday homes. Some 850 children attend the four elementary schools, and 150 a secondary school provided by the Kent County Council at Ramsgate, where 800 children belonging to the four sanitary districts in the Isle of Thanet are educated.

Cases of Poliomyelitis and Polio-encephalitis Notified (1926).

For the week ended—	In England and Wales.	In Kent.
September 4	43	1
„ 11	53	2
„ 18	77	5
„ 25	44	3
October 2	68	1
„ 9	51	5
„ 16	78	23
„ 23	89	37

Previous Cases in the District.

It is an interesting fact that during the five years ended 1925 only two cases of the disease were notified in the urban district, and they occurred in 1925; that no cases were notified in 1926 prior to October 14th; that no cases were notified during the first ten months of the year in the borough of Margate, in the adjacent rural district of the Isle of Thanet, and only two in the borough of Ramsgate.

Possibility of Infection being Introduced from Abroad.

I understand that there were severe and fatal outbreaks of poliomyelitis and polio-encephalitis in the neighbourhood of and along the coast of Brittany during the summer. It is possible that the infection was brought to France by American visitors. The boy who died in the school in Broadstairs first affected had spent his holidays in Brittany, and he may possibly have introduced the disease into the school. At another school the first case, an abortive one, was that of a boy who spent his holidays in Brittany. In a third school a boy who died had spent his holidays in Norway.

Inquiries were made as to whether any of the cases had been recently vaccinated. It was found, however, that none had been done.

It is well known that the disease may be conveyed from person to person by healthy carriers, and the investigations which were made in connexion with this outbreak tend to show more than ever the importance of this factor.

History of the Outbreak.

On October 14th I received eight notifications of cases at a private boarding school, one of a mistress in an adjoining girls' school, and of four cases in the town—two in two day schools. On the next day I received two notifications, one of these being a boy who attended the Ramsgate County School. On October 16th I had four notifications, two more private schools being affected. On October 18th I received nine notifications, five fresh schools being affected. On October 19th thirteen notifications were received, one other school being affected. On October 20th four cases were notified, one being a patient in a convalescent home. On October 21st three were notified; one of these belonged to one of the elementary schools. On October 23rd four were notified, two of these at another convalescent home. On October 25th three were notified. On October 26th four were notified, one of these in an elementary school. On October 27th two were notified; one of these attended an elementary school and one was in another private school. There was one notification on October 29th and one on November 11th. This makes a total of 63. One of the notifications was withdrawn, which leaves a total of 62. In addition to these cases, two boys from the private school first affected were removed to their homes and afterwards developed the complaint, and one of them died. Then there was the case of a waiter, aged 22, employed in a hotel in Broadstairs during the season, who left the town on October 6th, developed the disease on the 16th, and died in a London hospital on October 21st; and that of a young woman, aged 29, who stayed in Broadstairs from October 2nd to October 9th, was taken ill on the 18th, and died on the 22nd. Apparently she was not well during her stay in Broadstairs. These two cases were not notified. Then there was the case of the brother-in-law of the headmaster of one of the schools, who had been staying in Broadstairs for three weeks. He visited the school on October 10th and had lunch there. He left Broadstairs the following day and was taken ill with the complaint on October 16th (boys were taken ill in the school on October 13th). It will thus be seen that the total number of cases in connexion with the outbreak was probably not less than 67, and that the total number of private schools affected was thirteen. In these, thirty-five children were affected, one mistress, and two members of domestic staffs. There were three cases in the Ramsgate Secondary School; two in the Broadstairs Council School (Girls' and Infants' Departments); and one in St. Peter's Church of England School (Infant Department). In one convalescent home there were five cases (two children and three members of the staff), and in another convalescent home there was one case.

In addition to the above fifty cases there were twelve others not connected with schools or institutions, except indirectly—for example, one whose brother attended a school where a case occurred.

The following table shows the number in attendance and of cases in the various schools.

Boarding Schools.	No. in Attendance.	Cases.
A.—Boys	73	9 boys, 1 staff
B.—Girls	53	3 girls
C.—Girls	74	2 girls, 2 staff
D.—Boys	21	5
E.—Boys	28	1
Totals	249	23
Mixed Boarding and Day Schools.		
F.—Boys and girls	50	5
G.—Boys	42	1
H.—Boys	24	3
I.—Boys	27	1
J.—Girls	6	1
K.—Boys and girls	26	2
L.—Boys and girls	70	1
M.—Boys	73	1
Totals	318	15

On October 14th and the five following days thirty-one cases were notified in twelve private schools. The age of the oldest person notified was 30 and the youngest 1 year.

The numbers notified between the following ages were: From 1 to 5 years, 7; 5 to 10 years, 18; 10 to 15 years, 27; 15 to 20 years, 5; 20 to 25 years, 2; 25 to 30 years, 3—a total of 62 cases. The males numbered 38 and the females 24.

The number of cases removed to the Isle of Thanet Joint Hospital was nine. Of these, five belonged to a convalescent home, two were on the staffs of two private boarding schools, and of the two others one attended the Ramsgate County School and the other the Broadstairs Elementary School.

Deaths from Infantile Paralysis.

Following are brief notes of four cases of infantile paralysis in which death occurred.

1. A boy, aged 10, at a private boarding school, was taken ill on October 10th; temperature 102°. The following day the temperature was 101°, and his back was stiff. On October 12th he had symptoms of asthma in the morning; in the afternoon the head was retracted, and at 5 o'clock he had convulsions which lasted twelve minutes and were followed by death.

2. A woman, aged 28, a teacher at a girls' boarding school, attended St. Peter's Church on October 10th. She went to Ramsgate on October 11th, and was taken ill the following day at 6 p.m. She died at midnight on October 14th, from respiratory paralysis, after losing all reflexes and developing paralysis of the deltoid.

3. A boy, aged 8, a day scholar at a private day and boarding school, was taken ill with vomiting and coryza on October 10th. He continued getting about until October 15th, when he was seen by a doctor. His temperature was then 102°; he complained of severe headaches and some stiffness of the neck. The knee-jerks, which were present on October 16th, were absent on the following day; on this day the temperature was 101°, pulse 120, and nystagmus was present. On October 18th there was paralysis of both lower limbs and of most of the muscles of the upper limbs; the next day the diaphragm also was paralysed. On October 20th the temperature was below normal, pulse 120, respirations 40. On October 23rd the patient became cyanosed; pulse rate 160; he was conscious until a quarter of an hour before the end.

4. A boy, aged 5, who attended the infant department of an elementary school, was taken ill on October 25th. A doctor was sent for early on October 26th. The symptoms included paralysis of the palate, absence of knee-jerks, and stiffness of the neck. He died about 2.30 p.m. from paralysis of the respiratory centre.

The cases which were notified varied in intensity—some were very mild and had no paralysis, perhaps only a rise of temperature with nystagmus, others presented serious symptoms. Two boys who attended the same school and sat next to each other had the meningeal type of the disease, but both recovered. Others had paralysis of the lower limbs. In several cases the patients were taken ill with symptoms which were thought to be due to influenza. These subsided, but after four or five days the symptoms of infantile paralysis developed.

The date of onset of the earliest case notified was October 4th, but half the cases were taken ill between October 10th and 13th; then eighteen cases between October 14th and 18th; the remainder between October 19th and November 6th.

Most of the schools affected were situated in the northern portion of the district and near the sea. The school with the largest number of cases was the one situated nearest the sea.

The serious effect which is produced by an attack of infantile paralysis is, of course, the loss of power which results. Out of sixty-two cases notified in this outbreak, paralysis was noted in twenty-nine. As to how many of these patients will be permanently paralysed it is impossible to say.

As four deaths occurred out of the sixty-two cases notified, the mortality was 6.4 per cent., but if the outbreak is considered to have consisted of sixty-seven cases, then we have seven deaths, which gives a mortality of 10.4 per cent.

The interesting features of the outbreak were the facts:

(1) That the disease was limited mainly to the children attending private schools in the district, particularly boarding schools; that most of these schools were situated in the northern part of the district, and that the private schools had very little communication with each other.

(2) That the disease started almost simultaneously in all the schools affected, and that the outbreak ceased almost entirely at the end of a fortnight.

(3) That the disease did not spread to the adjoining districts.

(4) That the disease did not spread in the elementary schools.

It is now two months since the last case was notified, and there is every reason to believe that the urban district is free of infection.

EDUCATION OF THE ADOLESCENT.

THE Consultative Committee of the Board of Education has just published its Report on the Education of the Adolescent.[1] It is an extremely important and very interesting discussion of the subject. While it is, of course, primarily of interest to those who are directly concerned, whether as teachers or as administrators, with public education in England and Wales, it should make its appeal also to many others who are interested in a more general way in the bearing of our educational system on the social, economic, and political life of the community, as well as to those, as in Scotland and elsewhere, who have to do with an educational organization of a different character. The suggestions of this report, too, if carried into effect, must have a marked influence upon the school medical service in all its aspects, and involve repercussions, educational and medical, upon public health in general. No apology is needed, therefore, for commending its study to the medical profession as to others. The fact that the report extends to some three hundred and sixty pages in all need not be a deterrent, for it is pleasant to read, both as to print and as to style, and if the portions of the report which are of the nature of preface and appendix as well as those of an historical character are ignored, as they may well be by some readers, the actual number of pages to be read may be reduced to not many more than one hundred. Within that relatively small amount of reading matter there is contained abundant material for the consideration of all who are concerned for the welfare of the children, and so for the future welfare of the country.

The Position To-day.

The present position of the organization of public education in this country is as follows. All normal children are required to attend school from 5 years of age until the end of the school term in which they become 14, usually described as the age of 14+. Children who are physically or mentally defective must attend school from 7 to 16 years of age. Local authorities for elementary education are required to provide accommodation and suitable instruction for all these children, except that small proportion of them who are receiving a satisfactory education under some other auspices. There are other schools, carrying on education to the age of 16 or 18 years, which are aided or maintained by local authorities for higher education, either established by those authorities or of an older foundation. Usually at least 40 or 50 per cent. of the children in these "secondary" schools have come from the public elementary schools, and it is obligatory to provide in them a considerable number of free places each year for such children. These "free-placers" enter the secondary school as the result of an examination at the age of about 11 years. It is only recently that the obligation to attend school to the age of 14 years has not been subject to a considerable number of exemptions at the option of education authorities, and as a result of the stricter obligation it is found that a larger proportion of children than previously tend to remain at school beyond the compulsory age. For such of these children as have not entered secondary schools it is necessary to provide a suitable advanced curriculum, and most progressive authorities of populous places have provided this either by special classes or courses at the top of the ordinary school, or by drafting such children into schools (commonly known as central schools) with a special curriculum with some practical or vocational "bias," or, to a much smaller extent, into junior trade or technical schools in which the work aims at a substantial measure of personal craftsmanship of a character appropriate to local industries. The children are as a rule admitted to the advanced courses or to the central school as a result of the same examination as that for the free places in secondary schools—that is, at about 11 years of age.

"Elementary" and "Secondary" Education.

The Consultative Committee thus found that the distinction between "elementary education" as conducted in public elementary schools and in central schools on the one hand, and "secondary education" as conducted in secondary schools and technical schools on the other hand, was, in fact, breaking down, and that the condition of things is at present educationally anomalous and administratively absurd. The education given in some central schools under one code of regulations and one system of grants by one kind of authority does not differ fundamentally from that given in some secondary schools under a different code of regulations and a different system of grants by a different kind of authority. The Committee found, too, that it was the practically unanimous opinion of those who submitted evidence to it, whether administrators or teachers, that there should be a regrading of education into two phases: (1) primary education, the education of childhood, and (2) post-primary education, the education of adolescence, and that the division should be made in the average case at the age of 11+. Medical and psychological opinion will endorse this. Educational organization should be based on the actual facts of child development. The beginning of a new stage in education should, if possible, coincide with a new phase in the life of the individual, and, as the report says:

"By the time that the age of 11 or 12 has been reached children have given some indication of differences in interests and abilities sufficient to make it possible and desirable to cater for them by means of schools of varying types but which have, nevertheless, a broad common foundation."

The strong recommendation of the Committee on this matter is sure at no distant date to have practical effect given to it, in spite of certain formidable administrative difficulties which will be referred to later, and in spite of some awkward questions with regard to denominational religious instruction to which it may give rise in some instances.

Proposed Regrading and Reorganization.

Broadly, it is recommended that (in addition to the junior technical or trade schools which should be continued in suitable localities) the new post-primary or secondary education should be of two main types: (1) the "grammar school" type, corresponding to that given in the present "secondary schools" which, though they may vary considerably among themselves, follow in the main a predominantly literary or scientific curriculum and carry the education of their pupils forward to the age of 16+ or even 18+; (2) the "modern school" type, giving at least a three (preferably a four) years' course from the age of 11+, with a practical or vocational bias in the last year or two years. This second type of post-primary education might be given either in special schools, corresponding to the present central schools, or in some cases by separate and properly organized advanced courses in the ordinary school. This last alternative deserves careful consideration. The great majority of the Committee think that such an arrangement should be regarded as temporary or transitional, though they recognize that it will be necessary for some time to come. No doubt there are advantages in marking the new phase of education by the removal of the pupil to a different building, but there is force in the note written by Miss E. R. Conway, in which she is supported by the National Union of Teachers, that:

"The teaching of the older and brighter children acts as a stimulus to the staff, and their removal will destroy a source of interest for the teachers and of ambition for the children. The fact that older and younger children are dealt with in the same school building is also a valuable aid to character training, giving the older pupils that sense of responsibility to their younger and weaker colleagues which develops into the mutual care and consideration which is so helpful in the life of a community."

It is at all events clear that there may be local authorities in whose case the situation, accommodation, and arrangement of their schools, and the general character of their teaching staff, may make it both economically and educationally preferable to develop and equip advanced courses in their elementary school buildings (with sufficient division to mark the new phase) rather than to build new central or special schools, and that in some localities this may even be desirable as a permanent and not merely as a temporary arrangement.

The Age of Compulsory School Attendance.

Two important and interrelated questions at once arise from a consideration of this scheme for educational regrading and reorganization: (1) Should the age of compulsory school attendance be raised to 15 + or even 16 years? (2) What has become of the day continuation schools contemplated by the Education Act of 1918? The former question receives prominent consideration in the report: the latter is apparently ignored, perhaps because the Committee regarded it as an established fact that those schools would never materialize. Yet it remains true that under the consolidating Act of 1921 (Sections 75 to 79) it is the duty of education authorities to establish and maintain part-time day continuation schools for young persons already in employment, who were to be compelled to attend them for a certain number of hours each week between the ages of 14 and 18 years. Such schools were established for a short time in London and in Birmingham, and other authorities were preparing to establish them when the obligations were suspended. It is a fact, therefore, that this system of further education has had no chance of proving its worth, and there are those who, like Mr. H. A. L. Fisher and Sir Robert Blair, would prefer its re-establishment to any compulsory raising of the school age for whole-time attendance. There can be little doubt, however, that the Committee is right in taking for granted that the great majority of employers, parents, and teachers alike would prefer for the adolescents with whom they have to deal one year's further whole-time attendance at school rather than the compulsory part-time attendance extended over several years. The Committee makes the definite recommendation that "legislation should be passed fixing the age of 15 years as that up to which attendance at school will become obligatory after the lapse of five years, that is to say, at the beginning of the school year 1932," though three of the members, while agreeing in principle, do not agree that the changes should, or can, be effected in so short a period of time.

Unfortunately the President of the Board of Education has issued with the report a letter in which he declares that he has no intention whatever of adopting this recommendation; and this though there is no prospect of the alternative method of day continuation schools maturing. He points out, truly enough, that at present local education authorities have it in their power, with his sanction, to raise the school age in their own areas, and that only two authorities have actually availed themselves of this; but he omits to mention that the one definite pronouncement on this matter by the representatives of education authorities in conference has been "that it is not desirable to raise the school-leaving age to 15 unless the change is made compulsory over the whole country." (Association of Education Committees, June, 1924.) The reason behind this is that progressive authorities are prevented from adopting a by-law raising the age in their area because this would immediately be a handicap to their children in the labour market as compared with the children in neighbouring areas who could enter employment in local industries at the earlier age.

It is, of course, certain that the extension of compulsory school life by even one year would involve most authorities in a good deal of increased expense for accommodation, equipment, and teaching staff, though perhaps not so much as is commonly stated. This is the reason why long notice should be given, as suggested, of any extended obligation; and no doubt this is the real reason why the Minister, Lord Eustace Percy, opposes it. It must be recognized, too, that there is a relatively small proportion of children in the public elementary schools of a mental calibre which does not justify a continuance of school education beyond the present compulsory age. This, together with urgent economic considerations in some instances, would make necessary the continuance of the proviso allowing education authorities to grant exemption from attendance in suitable cases. The trouble is that without legislative compulsion, and with the present discouraging temper and restrictive

policy of the Board of Education, there will be large numbers of boys and girls whose further education would be an individual and national advantage, who will never have any opportunity of receiving it.

An Interesting Parallel.

One big administrative difficulty would arise in the adoption of the proposals of the Consultative Committee. Though temporary troubles may be surmounted by friendly arrangements between local education authorities, the existence within county areas of separate authorities for elementary and for higher education would have to disappear. The Committee recognizes and states this, and makes proposals to meet the situation. It is of very great interest to find that these proposals are almost exactly parallel to those made by the British Medical Association with regard to public health administration where similar difficulties arise. These are set out in some detail in the Memorandum of Evidence to be given before the Royal Committee on Local Government (SUPPLEMENT, January 30th, 1926, pp. 36-38), particularly in paragraphs 10, 11, and 16. It was there suggested that complete powers of public health administration should be given to areas that reach a certain minimum standard of population, and that for complete unification of such administration a radical revision of areas would be desirable, instituting larger areas arranged with some natural urban centre as the focus of each. The Association's memorandum even says—

"It seems probable also that areas so constituted would be equally suitable for the best provision and administration of education in its various forms. In each case it is possible that a few larger administrative groups or provinces would be desirable, in the one case for university or higher technical institutions, and in the other for the establishment of teaching hospitals."

The corresponding recommendations of the Consultative Committee are:

34. We recommend that at as early a date as possible legislation should be introduced for the transference to authorities for higher education of all powers and duties of those authorities for elementary education only which are concerned with areas that do not reach a certain minimum standard of population, and for the vesting of full powers in respect of higher education in those authorities for elementary education only which are concerned with areas that attain such a minimum standard.

35. Finally, we recommend that consideration should be given to the question whether it may not be a desirable objective of educational development that provincial authorities for education should be instituted, in which the authorities for elementary education only and the authorities for higher education shall both be ultimately merged.

It would be an immense gain, not only to administrative simplicity, but to practical efficiency, if reforms on these lines were carried out; and the reinforcement of the British Medical Association's somewhat radical proposals by these important recommendations of the Consultative Committee to the Board of Education is to be welcomed.

France.

[FROM OUR PARIS CORRESPONDENT.]

The Laennec Celebrations.

How ought a great man to be honoured? The question was asked long ago by King Ahasuerus, as may be read in the Book of Esther. Our age seems singularly wanting in imagination, for the answer of the modern Haman may be summed up in one single word—speeches. We have just been celebrating the centenary of Laennec by a flood of speeches, of the magnitude of which the official list gives only a feeble notion. A foreign delegate said to me that he had had to digest not less than forty "ragouts" of eloquence in three days, and he had still to go to the final banquet! It was considered that the memory of the great French clinician should be celebrated officially by the city of Paris, the head of the State, the Academy of Medicine, the Faculty of Medicine, various hospital organizations, and, lastly, the Pasteur Institute. The foreign delegates had no easy task, and nobody will be surprised to be told that it was Sir StClair Thomson who discharged it with the greatest success; he managed to establish a record both for brevity and for humour. He charmed his audience by declaring that he was doing his best to undermine the work of Laennec by the use of the bronchoscope, doing with that tube inside what Laennec had done with his tube outside. The famous first stethoscope used by Laennec was exhibited in the hall of the Academy of Medicine, as were many other touching personal souvenirs. It is not without interest to observe that Laennec spelt his name in the way it is spelt here, and pronounced it in two syllables. Very discreetly did some of the foreign delegates teach a lesson to the successors of Laennec, but so successfully that the Academy, in its report of the centenary, at last suppressed the unfortunate diaeresis. Among the speeches special attention ought perhaps to be drawn to Professor Calmette's remarkable review of his own researches in the vaccination of the new-born against tuberculosis. Is not the truest homage we can pay to our great dead to carry on their work? And has not Calmette found a suitable answer to the question put by Ahasuerus?

Vaccination and Encephalitis.

At a recent meeting of the Société Médicale des Hôpitaux M. Comby related a case of acute encephalitis occurring in relation to vaccination. The patient was a girl, aged 18 months, and the symptoms appeared twelve days after vaccination. Lumbar puncture yielded a fluid containing only four lymphocytes per cubic millimetre, 0.20 of albumin, and 0.50 of sugar. After five days of coma, accompanied by contractures, the patient recovered. About fifty analogous cases have been collected in which the results were less fortunate. Dr. Netter has argued that the vaccine was not the direct agent in producing the encephalitis, which he attributes to a secondary infection. Nevertheless, vaccinia is a general disease, and the inoculation of cerebral substance from patients who had died of the condition produced a vaccinal pustule in the rabbit. After full consideration of the subject Dr. Netter advises, now that we are able to use very virulent vaccines, that vaccination should be very lightly performed by a simple single scarification.

Martyrs of Medicine.

We have all been profoundly moved by learning of the death, at the age of 24, of Henri Vadon, a hospital intern in Paris. He was a young man who had already attracted the attention of his teachers by his brilliant intellect and by his capacity as a worker. He died of experimental cancer, if one may so say, after an accidental prick made when conducting a *post-mortem* examination on a person who had died of cancer. As Professor J. L. Faure has pointed out, this is the first authentic observation of inoculation of cancer in man, and deserves to find its place in literature as proof positive of the parasitic nature of cancer. Henri Vadon was not under a delusion as to the nature of the disease with which he had been attacked; he watched its progress from day to day, and continued to perform his duties and to carry on his researches to the extreme limit of his strength. His tragic fight against death lasted for over two years.

The BRITISH MEDICAL JOURNAL has already announced the attempt upon the life of M. Froment, professor of neurology at Lyons; readers will be glad to know that he is making satisfactory progress. Professor Froment was treated where he fell, in his own ward, and his first act when he was again allowed to begin to do some work was to inquire into the condition of his would-be assassin, who was also his patient.

G. MONOD.

England and Wales.

THE MANCHESTER COMMITTEE ON CANCER.

THE lecture by Professor A. H. Burgess on cancer of the gastro-intestinal tract, published in these columns on January 1st, was one of a set the Manchester Committee on Cancer arranged to be given during this winter session as part of its campaign of propaganda. The lectures are addressed to the medical profession, but the propaganda will eventually be extended to the public by various methods. The Manchester Committee owes its origin to the medical officer of health, Dr. R. Veitch Clark, who some time after the issue by the Ministry of Health of its memorandum on

cancer to local authorities called together a provisional committee which, with its subcommittees, held preliminary discussions. In December, 1924, it was decided to reconstitute the committee in a more formal manner so as to bring it into official relation with the bodies in the city of Manchester concerned with the problem of cancer in all its aspects. A communication was therefore sent to the various hospitals in Manchester, to the University, and to the Public Health Committee of the city council, and to some other bodies, asking them to nominate representatives. The reconstitution was completed towards the end of February, 1925.

The Manchester Committee on Cancer now consists of officially appointed professional and lay representatives from the Public Health Committee of the city, from the University, from the Manchester Royal Infirmary, the Christie Hospital and other large hospitals in the city, and the Radium Institute. The object of the committee is to establish a properly correlated and single effort in Manchester for cancer research and for the control and treatment of all cancer cases. In November, 1925, a public appeal for £20,000 was launched to cover the expenses of an agreed plan of work for a period of three years; as a result £12,000 was received, and the limited scheme which the pecuniary resources made possible was put into operation in May, 1926. The chairman of the committee is Dr. Veitch Clark, and the deputy chairman Sir William Milligan, who is also chairman of the Executive Subcommittee; a Research Subcommittee has been formed, with Dr. E. M. Brockbank as chairman, and Professor R. B. Wild as deputy chairman. Dr. C. C. Twort has been appointed pathologist to this committee; he will work at the University, and will have the assistance of a full-time chemist, Dr. Ing, Ph.D.Oxon., who has recently been engaged in conducting special researches on oils. Dr. Twort, who began duty in May, had completed the equipment of his laboratory at the end of July, and was then able to begin research work. The main line of experimental research to be undertaken is in connexion with the origin and prevention of mule-spinner's cancer, a condition which, as our readers are aware, is closely associated with the Lancashire cotton industry. Another line of work the committee has instituted is a special statistical inquiry, for which purpose two full-time investigators have been appointed—Dr. Gretta Mary Wardle and Dr. John Murray—to conduct certain specified pieces of work; both have had special experience in this direction. They will be guided by the Ministry of Health's memorandum on the results of treatment in cases of cancer of the breast for the years 1910-13 and 1919-1921, an analysis of which was published on August 14th, 1926 (p. 318). A regular and complete system of record-keeping in respect of all cases of cancer in the city is being established, and specimens from cases of cancer in the hospitals and in private practice will be collected for submission to the histologist in the hope that conclusions may be reached as to the efficiency of the treatment afforded to the different types of cancerous growths. Further, each case of cancer occurring in the city, or treated there, will be subjected to continuous supervision, so that any recurrence of the growth or intermediate condition associated with the cancer may be recognized at the earliest possible date and the patient referred immediately to the private medical practitioner, with a view to suitable treatment being provided without delay. At present the two special investigation officers mentioned are engaged in reviewing the records of the Manchester Royal Infirmary and the Christie Hospital; in this way 687 cases have already been investigated. The cases are followed up in the homes and the results obtained by treatment noted.

Dr. C. Powell White has been appointed histologist (part-time) to examine specimens from each case of cancer coming to the knowledge of the committee. This work is considered essential to ensure correct diagnosis, which is, of course, an important part of adequate and successful treatment. By the correlation of this information with that obtained from the records and specimens and the type of treatment adopted in each case knowledge of the best form of treatment of the different types of cancer will, it is hoped, be improved.

A special propaganda subcommittee has been appointed to take action with a view to informing the public on the subject of cancer, its incidence and treatment. The Public Health Committee of the city has delegated its statutory powers in this respect to the Committee on Cancer, and the Manchester Insurance Committee has sent a subscription to the funds for this specific purpose. A course of post-graduate lectures on cancer, for medical practitioners, of which Mr. Burgess's lecture was one, forms part of the general scheme. The course, which is given in association with the University of Manchester and the Manchester Royal Infirmary, will consist of twelve lectures; the first was given by Dr. Veitch Clark on October 1st, 1926, and the last two, on x rays and radium in the diagnosis and treatment of cancer, will be delivered in February. Leaflets for distribution to the general public are in course of preparation, and the question of public lectures on cancer is at present under consideration.

HEALTH OF LONDON IN 1925.

On August 21st, 1926 (p. 347), we reviewed that portion of Volume III of the Annual Report of the London County Council for 1925 which contains the reports of the county medical officer and school medical officer. The following observations refer to the remainder of the volume, which was published more recently as a separate part.

Under its tuberculosis scheme the County Council is itself responsible for the residential treatment of patients. It is reconditioning its institution at Grove Park, Lee, for advanced cases of both sexes. The metropolitan boroughs, on the other hand, provide dispensary treatment. One borough council proposed to equip its dispensary for natural and artificial sunlight treatment. While it declined to approve a grant for such equipment at a borough tuberculosis dispensary, the County Council took steps to provide this elsewhere in 1925.

Under the powers possessed by the Council, 2,300 samples of milk consigned to London railway termini from thirty-three counties were bacteriologically examined; 107 samples, or 4.6 per cent., contained tubercle bacilli. The Council's veterinary inspector visited 98 farms concerned, and examined 2,864 cows. Of these cows 53, or 1.8 per cent., were tuberculous or otherwise unhealthy; 30 others had been slaughtered. The County Council is the local authority for administering the Tuberculosis Order, 1925—which came into force on September 1st, 1925—in the county outside the City of London. The Order aims at the destruction of every cow suffering from tuberculosis of the udder or giving tuberculous milk, and of every bovine animal showing definite signs of tuberculosis. As the Council, under its General Powers Act of 1904, already had authority to seize and slaughter any cow suspected to be suffering from tuberculosis of the udder, the Order will not greatly modify its practice in this field. The Milk and Dairies (Consolidation) Act, 1915, which also came into operation on September 1st, 1925, provides for the repeal within one year of so much of any local Act as covers the same ground. The powers of the County Council, therefore, under Part IV of the London County Council (General Powers) Act, 1907, with respect to the taking and examination of samples of milk, were due to expire as at August 31st, 1925. The bulk of the new Act, as affecting London, will be administered by the metropolitan borough councils.

In connexion with the smoke nuisance, it was arranged during the year with the railway companies running steam-driven trains in London that a series of joint observations should be made from the footplates of engines by the Council's coal officers and officials of the companies. The observations showed that, while some smoke proceeding from locomotives may be the result of negligence, there are occasions when its emission cannot be entirely avoided. In the matter of main drainage, experiment has established the fact that London sewage responds well to activated sludge treatment. The sludge is sunk in the Black Deep of the Thames estuary. Allegations had been made that waste material deposited here by the Council and others was causing shoaling of the Edinburgh Channel, one of the principal access-ways to London for large ships; but the Board of Trade, having heard evidence during the

year, saw no reason to discontinue the present uses of the Deep. As regards housing, the Council in 1925 completed 2,023 houses and flats with accommodation for 14,848 persons. Between 1894 and the close of 1925 the output of the Council has been 21,178 tenements and houses and three lodging-houses, sufficient for 140,000 people. The programme of work in hand comprises 15,000 additional houses, apart from rehousing under slum clearance schemes.

GIFT TO ST. THOMAS'S HOSPITAL.

A contribution of £104,000 has been made to the general funds of St. Thomas's Hospital by Mr. W. R. Morris, in response to an appeal by Mr. George Roberts, a governor and one of the almoners, who has himself contributed generously. In an official statement by the secretary of the hospital it is announced that, while an outlay of about £175,000 a year is required, the assured annual income of the hospital only reaches the figure of £73,000, the balance having to be provided by voluntary help. The patients and those responsible for them contribute about £44,000 each year, so that a considerable balance remains to be raised. Mr. Morris's donation will therefore render substantial assistance in placing the finances of the hospital on a more satisfactory basis, and the deep gratitude of the governors has been expressed to him for his munificent gift at a time when help is so much needed.

NORTHAMPTON GENERAL HOSPITAL.

The 183rd annual report of the Northampton General Hospital records that the year 1925 was memorable in marking the completion of fifty years' work on the part of the Northamptonshire Hospital Week Committee in obtaining funds for the hospital. During that period a sum of nearly £133,500 was raised. It is noteworthy that in the first ten years of its existence the amount raised was £7,187, while during the fifth decade the contributions exceeded £88,400. On December 1st, 1925, the Lord Lieutenant for the county, the Marquess of Exeter, supported by the mayor and corporation of the borough, formally declared open the Crockett wards, and the Bishop of Peterborough dedicated the building. In order to secure an adequate annual income to maintain the services of the hospital efficiently, the committee is endeavouring to obtain a larger number of annual subscribers of one guinea and upwards, since the majority of the in-patients are totally unable to contribute towards their maintenance in hospital. The number of in-patients treated during the twelve months from August 1st, 1925, to July 31st, 1926, was 3,533, an increase of 511 over the preceding year. The ordinary income, £33,879, was, however, less by £741. The expenditure amounted to £36,497.

Scotland.

INFECTIOUS DISEASES IN SCOTLAND.

As mentioned last week, the commencement of an outbreak of scarlet fever at Grangemouth has been traced to a dairymaid. The epidemic has now reached considerable proportions, 104 cases having occurred by January 7th. As many as 26 cases had been notified in one day. It has been found necessary to utilize the hospitals of various neighbouring local authorities for the patients. The schools remain closed, and the Public Health Committee of Grangemouth Town Council has recommended that no social or other functions should be held meanwhile. The epidemic appears still to be of a mild type, and a large proportion of the persons affected are adults, some being over 50 years of age. An epidemic of measles has manifested itself in Edinburgh, where last week 140 cases were notified. The cases are generally of a mild type, but the more severe are being removed to hospital, especially from houses which are poor or overcrowded. A severe epidemic of measles occurred at the corresponding season last year, and in the present epidemic many children who then escaped are now being attacked.

ROYAL INFIRMARY OF EDINBURGH.

At the annual general meeting of the Court of Contributors to the Royal Infirmary of Edinburgh it was reported that negotiations for the purchase of the site of George Watson's College, which is situated immediately to the west of the infirmary, have now been completed. As has already been announced, it is intended to use a portion of the college site for the erection of a new gynaecological and maternity hospital, and arrangements have been made to amalgamate the Royal Infirmary and the Royal Maternity and Simpson Memorial Hospital. The conditions of purchase, which were described some time ago, included a gift of £10,000 from Sir John Findlay to adjust the difference between the price which the infirmary was prepared to give and that which the Merchant Company was prepared to accept for the college and its site. It is understood that it will not be possible to adapt the existing building of the college for hospital purposes, and that it will therefore be demolished. The site will not be available for several years.

The report presented to the recent annual general meeting of the League of Subscribers to the Royal Infirmary showed that a total sum of £21,382 had been gathered from groups of employees in public works and business establishments, and from staffs of schools, banks, and Government offices. This was £26 more than in the previous year, and would, it was stated, have been much larger but for the depressed industrial conditions connected with the coal strike. Of the total, £15,862 was raised in Edinburgh, and the remainder from country districts. The number of workers who contributed was 1,406. The largest contribution was that of the London and North-Eastern Railway Company workers, who subscribed £2,273. Since the institution of the league eight years ago the contributions had increased almost fivefold, and altogether a total of £137,574 had been collected. These figures do not include contributions from miners in the Lothians and Fifeshire, who for many years have contributed systematically; in a normal working year a sum of £15,000 had been regularly subscribed from the coal and shale workers. Sheriff G. L. Crole, a member of the board of management, said that the managers of the Royal Infirmary were greatly encouraged by the practical interest that the workers themselves took in a hospital which was peculiarly their own. It was reckoned that the amount lost by the coal stoppage and industrial unrest had been £7,555. Expenditure had also gone up, and a serious item had been the outlay for 6,000 tons of coal used by the Infirmary during the year at an average price of 66s. a ton, but at a cost of 91s. 8d. a ton during the strike. Fortunately, it had been possible to make savings to the extent of £4,000 in various departments, and the total increase in expenditure had been thereby reduced to £2,149. It had been possible to show a credit balance on the whole year's accounts amounting to £14,600. The negotiations with the Edinburgh Merchant Company regarding the purchase of George Watson's College would, he believed, soon be completed. The college would have to be pulled down and the Infirmary would not get entry upon the site for at least five years, but the ground would ultimately be of great use for extensions. There would probably be a large new maternity and gynaecological hospital on the site, and ninety beds would be freed for the surgical department. There would also be space to build a new nurses' home, which was urgently required.

WAR PENSIONS HOSPITAL.

The Glasgow Town Council has agreed to extend for one year the tenancy of the ground at Bellahouston Park at present occupied by the War Pensions Hospital. An application had been made on behalf of the Government for a lease of five years from Whit-Sunday, 1927, and the agreement to continue the lease for one year is a compromise reached in consideration of the large amount of work which is still being done at this hospital. Sir George T. Beatson, chairman of Glasgow War Pensions Committee, headed a deputation to the town council, and urged upon this body the importance of continuing the hospital. He stated that 200 beds were still occupied, that 1,284 cases had been

treated during the past year, and that 491 operations had been performed in the hospital. He did not think that the civil hospitals would be able to undertake this work, and it would be a difficult and costly matter to find a new institution.

NURSING SERVICES IN SCOTLAND.

At the thirty-eighth annual meeting of the council of the Scottish Branch of the Queen Victoria's Jubilee Institute for Nurses, which was held in Glasgow last month, Mr. Ewan Macpherson, chairman of the Scottish Board of Health, moving the adoption of the report, entered a plea for greater co-ordination between the services undertaken by the nurses of this institute and the work of health visitors under local authorities. It had been found possible in some counties and in one or two burghs to make arrangements under which the district nurses carried out as part of their duties the work of health visitors. There were some 400 district nurses acting as part-time health visitors, although certain local authorities felt that the work could be done better by their own whole-time visitors, of whom there were between 400 and 500 in Scotland. The Board of Health had done everything in its power to encourage co-ordination. The Countess of Mar and Kellie, who was in the chair, stated that there were now 418 nursing associations, employing 802 nurses, affiliated to the institute. These nurses had undertaken nearly 100,000 cases during the past year, upon whom 1,750,000 visits had been paid. This was an increase of 162,000 visits. In addition 300,000 visits had been paid in connexion with public health work, including child welfare. In response to the appeal in connexion with a national memorial to Queen Alexandra, approximately £75,000 had now been received out of the £150,000 aimed at. The money collected would all be spent in Scotland, where some 600 additional district nurses were required. When this was achieved every corner in Scotland would have the attention of skilled nurses.

Correspondence.

PHARYNGEAL DIVERTICULA.

SIR,—In your issue of last week Dr. William Hill questions my opinion that the tumour in the case published by Godlee and Bucknall (*Lancet*, 1901) under the title of "*A pharyngeal pouch of large size removed by operation*," was a cervical air sac originating from the laryngeal ventricle, and not a pharyngeal diverticulum.

Henle (Breslau), in 1904, recorded a similar case of an elderly man, who for ten years had suffered from an "aerial tumour" on the right side of the neck, which had gradually developed. It extended upwards, under, and beyond the angle of the jaw, and downwards close to the clavicle. Its connexion with the larynx was shown to exist by a canal through the thyro-hyoid membrane.

These cases, of which a considerable number have been recorded, represent reversions to the condition present in the ape, and it was to these air sacs that Virchow gave the name of "ventricular laryngoceles."

May I say at once that my opinion was not formed in a casual way, nor on the bare facts, as suggested by Dr. Hill, that the sac contained air, and that its neck was traced up to the thyro-hyoid membrane, though this may have appeared so since I was unable to enter into details owing to the short time at my disposal during the discussion on his paper at the British Medical Association meeting at Nottingham.

If Dr William Hill will refresh his memory by referring to my monograph "The so-called prolapse of the laryngeal ventricle, and eversion of the sacculus," a paper read at the third summer meeting of the Section of Laryngology, Royal Society of Medicine, in June, 1921, and published *in extenso* in the *Journal of Laryngology and Otology* in June, 1922, he will find that I touched on the subject of laryngoceles, and under this heading I referred, in considerable detail, to the case under dispute. Before re-grouping this case under that heading very careful consideration was given to all the evidence obtainable, as also to other cases recorded. The skilled advice and support of the late Professor S. G. Shattock—the greatest pathologist since the days of Virchow—was also sought and obtained. Everyone knows with what meticulous care he always investigated any problem or case submitted to him before he expressed any final opinion. It appears to me very unlikely that his opinion was wrong.

In any case I am afraid that Dr. William Hill has not yet convinced me that I have erred in so regrouping this case, since all the evidence he has brought forward in favour of the air sac being a pharyngocele, with perhaps the exception of the microscopical report, equally favour the assumption, and in my opinion more so, that the tumour was a laryngocele. Rare as laryngeal sacs are in man, I believe I am correct in stating that cervical air sacs of pharyngeal origin are rarer still

In the case recorded by Godlee and Bucknall an indirect laryngoscopic examination showed no abnormality in the larynx, nor would one expect to find any abnormality in the case of either a pharyngocele or a laryngocele. If, however, this case had occurred at the present day, and not during the early days of endoscopy, and an investigation had been carried out by the direct method of examination in conjunction with the passage of a probe through the thyro-hyoid membrane, it is possible that the probe would have been detected held up in the ventricle of the larynx. It appears to me to be much more likely that the deglutitory symptoms which Dr. William Hill refers to were caused by the pressure of the tense air sac on the pharynx, rather than "tumefaction due to inflation of the tissues of the faucial pillar and adjacent side of the pharynx." Has this latter condition ever been observed in connexion with a pharyngeal air sac? I doubt it.

The rapid increase in size of the air sac in the short space of six months from a tumour described as looking, when first seen, like an enlarged thyroid lobe, to an enormous sac extending to the middle line of the neck, the posterior border of the sterno-mastoid muscle, up to the angle of the jaw, and down to the clavicle, is surely strong evidence of its laryngeal origin and connexion. Such rapid increase in size could hardly occur by inflation through a small internal opening in the region of the posterior faucial pillar, especially if this opening—as suggested by Dr. William Hill—was at the same time obstructed by tumefaction.

I agree with Dr. William Hill that Godlee and Bucknall were undoubtedly aware of the existence of cervical air sacs originating from the ventricle of the larynx, but this does not exclude the possibility that, impressed with the idea that the tumour was connected with the pharynx, they did not give sufficient thought or consideration to the possibility of its origin from the laryngeal ventricle. Throughout the notes of their case there is not even a suggestion made by them of this possibility.

So far as the microscopical evidence is concerned it would appear quite possible that, under the impression that the air sac communicated with the pharynx, the glands were taken to be muco-salivary instead of mucous glands, with which they might have been readily confused. As is well known, the sacculus ventriculi laryngis contains a large number of mucous glands.

Since the publication of Dr. William Hill's letter I have discussed the case with Mr. Lawrence, at the Royal College of Surgeons, and he is also inclined to agree with Professor Shattock. He considered that it would be most interesting to have the microscopical section re-examined with a view to clearing up any discrepancy in the gland structure. I have therefore communicated with University College Hospital in the hope that the slide can be traced. If it is traced and definite muco-salivary glands are found in the section then, and only then, will I believe that Dr. William Hill is right, for the presence of these glands would distinctly suggest, if not confirm, the pharyngeal origin of this air sac. I shall then consider that he has proved his case. On the other hand, if they are found to be mucous glands, I have no doubt that Dr. William Hill will do the same.

I wish to take this opportunity of correcting an error in Dr. William Hill's reply to the discussion on his paper at the Nottingham Meeting (see BRITISH MEDICAL JOURNAL,

1926, ii, pp. 1171-72). He says "the suggestion of Keith, mentioned by Dr. Irwin Moore, that 'pneumatocele' was a preferable term to 'aerocele' he was prepared to accept, but he could not agree with the suggestion of Dr. Moore, following Sir Arthur Keith, that the pneumatocele recorded by Godlee and Bucknall was a laryngocele." These opinions were not expressed by Sir Arthur Keith but by Professor Shattock.—I am, etc.,

London, W.1, Jan. 11th. IRWIN MOORE.

MEDICAL POSTS IN INDIA.

SIR,—From time to time advertisements appear in the JOURNAL inviting applications for medical posts in India. Intending applicants for any such would be well advised carefully to consider the terms offered. In the JOURNAL dated November 27th, 1926, under the heading "Lucknow University," applications are invited for the post of professor of anatomy. The terms offered are Rs.1,450 a month; passage money is not mentioned, but it is definitely laid down that private practice is not allowed. From this salary 8 per cent. is to be deducted to go to the university provident fund, so that the salary is in reality Rs.1,334. There are two more deductions, neither of which is mentioned; these are income tax at 9 pies per rupee, which amounts to Rs.62½ a month, and profession tax, which is not under Rs.10 a month. The net salary is thus Rs.1,261 and 12 annas, say Rs.1,260. It is improbable that any house under Rs.150 a month will be available. A motor car is absolutely essential; its cost to keep and run, exclusive of depreciation, will be about Rs.200 a month after purchase. Clubs will come to Rs.100 at the very minimum, and servants not less than Rs.200 monthly. The total is Rs.650; this leaves only Rs.610 a month for the purchase of food, clothes, and the hire or purchase of furniture. The result of all these deductions and expenses will be that possibly, after exercising great and uncomfortable economy, the amount left over each month will come to Rs.300, which equals just over £20.

If by chance the applicant is married there would be the necessity of keeping his family in the hills for at least four months in the year, because Lucknow is impossible in the hot weather. On the pay offered this could not be done. The pay is not a living wage, as any "successful" applicant would find to his sorrow.

On a par with the above were the recently advertised vacancies for an entomologist and one or two similar scientific posts in Calcutta—a town where the expenses would come to at least three times those of Lucknow.

As it is quite impossible for anyone who has never been in the East to have any conception of what he will be up against, it is only fair that the examples given should be made public.—I am, etc.,

December 16th, 1926. OBSERVER.

THE SMALL HOSPITAL.

SIR,—It would warm many of our hearts to see in your mighty JOURNAL a plea for the really small and efficient hospital. The big hospital authorities who have now command of the situation seem determined to despise and make difficult the position of these hospitals, and yet I believe that from the point of view of maintaining the efficiency of the medical profession generally and getting improved treatment of the sick, the small local hospital has a very strong case.

There are two movements on foot to-day which will tell directly against these hospitals.

1. The training of nurses. None of this training in such a hospital counts now, though six months' training under proper conditions would be very valuable. The consequence is that the obtaining of probationers to start in a small hospital is now very difficult.

2. The new pension scheme. This scheme, in my opinion, is going to be of very little use to nurses. It is a scheme conceived in the interest of whole-time officials—a good thing, no doubt, but not understood as the main object. The effect on the small hospitals will be to add considerably to the cost of administration, as they will have to join in, but the premiums they will have to pay will be paid simply in order to exist—they will not be of any benefit to them. The scheme will in the end simply mean an addition to the salaries of the full-time official, and perhaps to a few of the best-paid nurses in the large hospitals.

It is astonishing how difficult it is to get the ear of administrators; they love the easy and the big thing, but the small local hospital is a very human institution which is worth preserving.—I am, etc.,

Letchworth, Jan. 2nd. NORMAN MACFADYEN.

DIET FOR DIABETICS.

SIR,—I read with interest the reviews of *The Diabetic Life* and *Self-Care for the Diabetic* in your issue of January 1st (p. 18), but was surprised to find the two following remarks stated as if they were proven and generally accepted, at least outside Great Britain—namely: "... the severest cases may, with the help of insulin, take considerable quantities of white or brown bread with advantage to their nutrition"; and "it begins to be time that 'high fat' diets for diabetics gave place to ordinary diets with adequate insulin." These statements by your reviewer would give the impression that the above method of treatment has been widely accepted as being the best. It has certainly been advocated by a few workers in France and America, but has been rejected as unsuitable by the great majority of workers on the Continent, America, and Great Britain. In common with many others, I tried the high carbohydrate method in the early days of insulin, and found it unsuitable in all except the mildest cases for the following reasons: (1) A marked hyperglycaemia resulted except during a few hours of the day when insulin action was at its maximum; (2) the liability to unpleasant hypoglycaemic reactions was frequent if enough insulin was given to bring the blood sugar anywhere near normal; (3) the increased expense of and local discomfort from the large and more frequent doses of insulin were a considerable handicap.

My reason for writing this note is to correct the impression that high carbohydrate diets and large doses of insulin have been proved and generally accepted as the best form of treatment. On the contrary, the "very English attitude" of giving moderate amounts of carbohydrate, total calories, and insulin is widely accepted in all countries as the most practical and satisfactory.—I am, etc.,

G. A. HARRISON.

Department of Chemical Pathology, St. Bartholomew's Hospital, Jan. 8th.

MONGOLIAN DEFECTIVES.

SIR,—In your issue of December 4th, 1926 (p. 1080), under the above heading, Dr. Crookshank states that "the homologies between the Mongolian defective, the racial Mongol, and the orang are indisputable." He further mentions that all good Darwinians accept as axiomatic the assumption that homologies prove descent.

Now, is there not another factor in this question which is even of more importance—namely, the order of development of the principal organs? The comparison of man with the anthropomorphous apes brings to light a very important fact—namely, the existence of an inverse order in the development of the principal organs. In man the sphenoidal angle of Virchow diminishes from the time of birth, whilst in the ape it is always increasing. A similar contrast has been remarked by Gratiolet upon the brain itself.

In the ape the temporal sphenoidal convolutions, which form the middle lobe, make their appearance and are completed before the anterior convolutions which form the frontal lobe. In man, on the contrary, the frontal convolutions are the first to appear, and those of the middle lobe are found later.

It is evident that an organized being cannot be a descendant of another whose development is in an inverse order to its own. Consequently, man cannot be considered as the descendant of any simian type.—I am, etc.,

REGINALD COCK, M.R.C.S.Eng.

London, E.2, Dec. 31st, 1926.

THE AGE INCIDENCE OF RHEUMATISM.

SIR,—The most recent observations upon the age incidence of rheumatism agree in stressing the early age in childhood at which symptoms appear, and the interesting letter of Dr. K. Simpson in the JOURNAL for January 1st (p. 42) lends further support to this conclusion.

One of the most urgent problems in medicine is that of heart disease in childhood. Modern statistics unite to show the extreme frequency with which carditis is associated with the initial onset of rheumatism. Thus, out of 100 fatal cases of rheumatism in children under 12, Poynton found *post-mortem* evidences of active heart disease in no less than 86. More recently, Mackie has investigated in New York 366 cases of rheumatic fever in children. Of these, 78.1 per cent. of children between 5 and 10 manifested signs of heart disease during the first attack, whilst between 10 and 15 the percentage rose to 79.2. This being so, our primary aim should be to prevent the first attack. Acute rheumatism being so markedly hereditary and familial in distribution, we should concentrate upon children coming of such parentage in the endeavour to raise their resistance to the rheumatic virus, of whatever nature this be; for to such procedure only can the term "prevention" be truly applied. In this regard I agree with Llewellyn that most of what has been written on the prevention of rheumatic heart disease deals neither with the prevention of rheumatism nor of heart disease, but with their arrest or control when either or both are actually present.

In order, then, effectively to cope with the problem of the potentially rheumatic child it is essential that the signs which point to a possible onset should be detected at the earliest opportunity. To wait for the development of definite stigmata of the disease is to lose much valuable time. It is probable that rheumatism resembles tuberculosis in that the seeds of disease become sown in soil which is rendered suitable for their germination by faulty hygiene and other environmental factors from infancy onwards.

Between the ages of 2 and 5 there is a gap in continuity of medical supervision. This gap should be bridged, and to this end a "children's cardiac clinic" was instituted last year under my direction at the St. Marylebone General Dispensary to deal particularly with the type of child generally regarded as "rheumatic." Parents are encouraged to bring their children for examination whenever possible prior to the manifestation of rheumatic symptoms, and for treatment where the disease already exists. The preventive aspect is held to be the prime objective. By timely advice to parents, together with the institution of appropriate therapy to raise the *vis resistentiae* of the child against unfavourable climatic and other influences, it is believed that weakly children of rheumatic stock may themselves be aided to work out their own immunity.—I am, etc.,

London, W.1, Jan. 6th. J. F. HALLS DALLY.

ANTIGENS FOR THERAPEUTIC IMMUNIZATION.

SIR,—Messrs. Parke, Davis and Co. have made the mistake of taking my strictures in a personal sense. This is in no way correct. It was the *system* whereby uncontrolled vaccine products can be put on the market that I was indicting and not this particular firm. As a matter of fact, I have a very great respect for Messrs. Parke, Davis and Co.'s work.—I am, etc.,

Eastbourne, Jan. 9th. GEOFFREY SHERA.

The Services.

DEATHS IN THE SERVICES.

MAJOR WILFRID COWAN NIMMO, R.A.M.C. (ret.), died in Queen Mary's Hospital at Roehampton on January 2nd, aged 47. He was born on August 8th, 1879, was educated at Westminster Hospital, where he gained an entrance scholarship, and took the M.R.C.S. and L.R.C.P.Lond. in 1903. After serving as house-surgeon and as resident obstetrical assistant at Westminster Hospital, he entered the R.A.M.C. as lieutenant in 1905, and attained the rank of major in 1915; he was placed on temporary half-pay on account of ill health in 1925, and retired three months later (July 31st). He served as a surgical dresser in the Imperial Yeomanry Field Hospital in South Africa in 1900-1, and also throughout the recent great war, being mentioned in dispatches in the *London Gazette* of October 19th, 1914.

Obituary.

C. EDWARD WALLIS, M.R.C.S., L.R.C.P., L.D.S.,

Senior Dental Surgeon, King's College Hospital.

We much regret to announce that Mr. Edward Wallis, senior dental surgeon and lecturer on dental surgery at King's College Hospital, died in that hospital from bronchopneumonia on the night of January 4th. His name will long be associated with the dental clinics of the London County Council, to which he devoted a large part of his time and energy from their inception twenty-five years ago. He will be remembered also as one who in his life and work exemplified the fact that dentistry is a part of medicine.

Charles Edward Wallis, eldest son of the late Augustus Wallis, was born in London in 1868. From Bedford Grammar School he went to King's College, London, and worked as a student in the old hospital building behind the Law Courts while Lister was still in charge of surgical wards there. Having obtained the M.R.C.S. and L.R.C.P. diplomas in 1894, he went for the first of many voyages, as ship surgeon, to the Arctic regions and the tropics, Canada, the Cape, and the United States. After a further period of study in Paris and at the Royal Dental Hospital, he took the L.D.S. in 1897, and decided to start practice in London as a dental surgeon. Election to the visiting staff of King's College Hospital and of the Victoria Hospital for Children soon followed, and at this early stage in his career he became impressed with the possibilities of oral hygiene in the young. A part-time post in the Public Health Department of the London County Council gave him the opportunity to make investigations, and in 1907 he presented a report to the International Congress of School Hygiene on the condition of children's teeth in the elementary schools of the metropolis. In 1911 he was appointed to supervise the school dental clinics set up by the London County Council, and as a result of this experience he wrote an account of the foundation and management of such clinics for the guidance of others. He published also several papers on the care of the teeth in public elementary schools, and contributed the article on dental care to Newsholme's *School Hygiene*.

These activities by no means used up Wallis's capacity for work. He was a member of the representative board of the British Dental Association, and for some years chairman of its editorial committee; he served on the International Committee for Oral Hygiene, and was consulting dental surgeon to a number of public institutions and charities. For some years he lectured on surgery to the nursing staff of the Victoria Hospital for Children, and in many other ways maintained contact with medicine as a whole. Thus he was a frequent attendant at medical meetings, and had been vice-president of the Chelsea Clinical Society and of the Medical Officers of Schools Association. As a Fellow of the Royal Society of Medicine he took an active part in the work of the Odontological Section, and served on the council of the History of Medicine Section. Indeed, historical subjects always made a strong appeal to him; he was an enthusiastic archaeologist, and had a wide knowledge of old London and old Paris. At the Annual Meeting of the British Medical Association in Birmingham in 1911 he was vice-president of the Section of Odontology. A few years later he was elected to the Metropolitan Counties Branch Council, and from 1916 onwards he held office in the Marylebone Division, first as honorary secretary, then as vice-chairman, later as chairman, and throughout as representative of the Division in the Representative Body. Since 1920 he had been a member of the Journal Committee, and his friendly interest in the work of the JOURNAL could always be counted upon.

Dr. E. GRAHAM LITTLE, M.P., in a tribute to Mr. Wallis's memory, speaks of his wide range of information and refers in particular to a lecture on the art of war in Rome which Mr. Wallis founded on the fine quarto volume *De re militari* published in the year of Shakespeare's death

by Justus Lepsius. This lecture, which had been delivered originally to the Casual Club in London, Mr. Wallis afterwards gave at many places along the Western front in France. Dr. Little also refers to Mr. Wallis's paper on ancient dentistry given to the Royal Society of Medicine, and mentions that he was engaged at the time of his death in preparing an essay on Harley Street, for which he had been collecting material for many years. Dr. Little concludes his tributes as follows: In his professional work Wallis enjoyed the respect and confidence of the whole profession. He never spared himself, was singularly indifferent to pecuniary rewards, and was always ready to do a kindness. His courage in facing persistent ill health was such that even his most intimate friends were often unaware that he was ill; pain never dimmed the brightness of one of the gayest and most cheerful spirits that our generation has produced.

Mr. BISHOP HARMAN writes: A record of long and consistent work such as that of C. E. Wallis is impressive. But to those who knew Wallis intimately the impress of his personality was still greater. He was a man of even temper, genial, kindly, with ever a smile of greeting. Even when his health and vitality was at the lowest, when illness confined him to the wards of his hospital, King's, he would still present a smile to his visitor. To meet him at the meetings of the Association was a pleasure. His gift did not lie in speech or debate, though he could hold his own when moved to the effort; but he had a flair for general converse, such as marks the beginnings and endings of meetings; then his interest was obvious, and kindly suggestions came freely, and not infrequently bore good fruit. The Marylebone Division will miss him, so also will the Metropolitan Counties Branch Council, and not a few members of the Representative Body. One of his chief hobbies lay in the discovery of old social interests. A walk with him about the old streets behind the former Association House and round Covent Garden was a delight and a source of unfailing illumination.

SIR HARRY EDWARD DIXEY, D.L., M.D.,

Chairman, King Edward VII Memorial Sanatorium, Worcestershire.

WE regret to announce the sudden death, on January 6th, of Sir Harry Dixey, at his residence in Malvern, in his seventy-fourth year.

Harry Edward Dixey, who was born in 1853, was the son of the late Charles Anderson Dixey of Highgate. He was educated at Highgate School and the University of Aberdeen, where he graduated M.B., C.M. in 1878, proceeding M.D. in 1881. He held the post of house-surgeon to the Preston Royal Infirmary, after which he began to practise at Droitwich and Malvern, where his professional ability and keen interest in public life won him a very distinguished position. For administrative work he showed remarkable talent. He held the chairmanship of the St. John Brine Bath Hospital in Droitwich, and of the King Edward VII Memorial Sanatorium for Worcestershire. He was also chairman of the Worcester City and County Nursing Association. He found time to play an active part in local government and was an alderman of the Worcestershire County Council; he was a deputy lieutenant for the county, and a justice of the peace, and in 1921 he was appointed sheriff. In previous years he had been an active supporter of the Volunteer movement, holding a commission as surgeon captain in the 8th Worcestershire Volunteer Regiment. He had long been a member of the Worcester Division of the British Medical Association, and served as its representative from 1906 to 1910. He was president of the Worcester and Hereford Branch in 1899, and a member of the Parliamentary Bills Committee in 1900-1.

His kindness and tact, together with his skill in various forms of organizing and administrative work, was widely recognized and highly appreciated. In recognition of his distinguished public services the honour of knighthood was conferred upon him last year. He married Ellen Mary, daughter of Mr. J. Dyson Perrins of Malvern.

Dr. JAMES JARDINE, who died at Richmond, Surrey, on December 7th, 1926, in his eighty-first year, was educated at Edinburgh University and at the Royal College of Surgeons, Edinburgh, where he graduated M.B., C.M. in 1871. In the same year he was appointed parochial medical officer of Middlebie in Dumfriesshire, and in 1874 became surgeon to the British Consulate in Kiu Kiang, China, where he remained till 1880. From 1882 until a few years before his death he practised in Richmond and helped to found the Richmond Nursing Guild. Always keenly interested in gynaecology, Dr. Jardine was elected, in 1904, a member of the council of the British Gynaecological Society. For many years he was a Fellow of the Royal Society of Medicine, and a member of the British Medical Association. His conscientious keenness in clinical investigation won him the respect and affection of his patients, by whom he will be greatly missed. He leaves a widow, three sons, one of whom is in the medical profession, and two daughters.

Dr. WILLIAM MILNE ANDERSON, who died on December 29th, 1926, aged 68, was the third son of the late Alexander Anderson, Esq., of Skene, Aberdeenshire, and younger brother of Lieut.-Colonel James Anderson, R.A.M.C.(ret.). He was educated at Aberdeen Grammar School and University, where he graduated M.B., C.M. in 1881. He held the posts of house-physician and house-surgeon at the West London Hospital. In 1886 he commenced private practice at Dulwich, where he held several local medical appointments. He was for many years a member of the British Medical Association and of the West London Medico-Chirurgical Society, and contributed several papers to medical journals. Dr. Milne Anderson's personality endeared him to his many patients and friends. He was very hard-working and led a strenuous professional life. Overwork during the war caused his health to fail, and in 1920 he retired to live at Alford in Aberdeenshire, where he hoped to regain health. He improved for a time, but became eventually a confirmed invalid. He leaves a widow, two daughters and a son.

Universities and Colleges.

UNIVERSITY OF CAMBRIDGE.

THE following candidates have been approved at the examination indicated:

DIPLOMA IN MEDICAL RADIOLOGY AND ELECTROLOGY (*Part I.*—
P. Bauwens, E. E. Carter, G. Chambers, J. C. Coutts, A. M Craib,
R. M [illegible] F. Cummins, H. Fisher, N. Fram,
D. B one, W. H. Hudson, J. J. Luddy,
A. T. " ansky, R. D. Saigol, W. H. Steele,
E. J. Yeo.

UNIVERSITY OF LONDON.

UNIVERSITY COLLEGE.

THE University College Committee, with the authority of the Senate, has accepted a gift of £500 from Lady Godlee for the foundation of a Rickman Godlee lectureship, in memory of the late Sir Rickman Godlee, Bt., F.R.C.S., a Fellow of the College.

The following distinctions and awards have been reported to the committee: The Professor of Anatomy, Dr. G. Elliot Smith, to be Huxley Lecturer at the University of Birmingham for the current session; the Royal Medal of the Royal Society has been awarded to Professor A. V. Hill; the Symington Prize for Anatomy of the Queen's University, Belfast, has, on the advice of the council of the Anatomical Society of Great Britain and Ireland, been awarded to Dr. H. Woollard.

The following candidates have been approved at the examinations indicated:

M.D. (*Branch I,* [illegible] B. Cullinan,
F. Davies, V. Fe J. Kohlyar,
W. A. Robb, N. *ychological*
Medicine): Em *nd Diseases*
of Women): H. Stephens.
(*Branch V, State Medicine*): D. Davidson.
M.S.—(*Branch I, Surgery*).—G. F. Gibberd, W. R. Spurrell.

UNIVERSITY OF LIVERPOOL.

THE following candidates have been approved at the examination indicated:

D.P.H.—(*New Regulations*): J. S. Bradshaw, Helen Standring, S. A. Talib, O. F. Thomas, T. S. Townsend. (*Old Regulations*): Olive L. Jones, Eleanor Lancelot, Vera M. Macfarlane.

Medical News.

COLONEL SIR JOHN LYNN-THOMAS, K.B.E., C.B., C.M.G., F.R.C.S., has been appointed a Deputy-Lieutenant for the County of Cardigan.

THE sixth international congress of the history of medicine will be held at Leyden and Amsterdam from July 18th to 23rd, 1927, under the patronage of the Prince of the Netherlands, with Dr. J. G. De Lint as president. Those intending to join the congress should send their names to the secretary, Dr. J. E. Kroon, Stationsweg 25, Leyden, before April 1st. The subscription, which is 10 florins for members of the International Society of the History of Medicine, 5 florins for their relatives and medical students, and 12.50 florins for others, should be sent to the treasurer, Dr. F. W. T. Hunger, Van Eeghenstraat 52, Amsterdam.

AT a meeting of the Society of Medical Officers of Health to be held at 1, Upper Montague Street, Russell Square, W.C., on Friday, January 21st, at 5 p.m., there will be a discussion on the education of the public in regard to modern methods of disease prevention (premunization, immunization, etc.). Different points of view will be presented by the following speakers: The government department, Dr. S. Monckton Copeman, F.R.S.; the medical officer of health, Dr. C. W. Hutt; the press, Lord Riddell; the public, Dean Inge; the laboratory director, Professor J. C. G. Ledingham, F.R.S.

THE Post-Graduate Hostel's programme for next week includes an address on Tuesday by Dr. J. M. T. Finney of Baltimore on the surgery of gastric and duodenal ulcer. On Wednesday Mr. Foster Moore will lecture on acute glaucoma, and on Thursday Professor A. W. Sheen will discuss the early recognition of surgical emergencies. The meetings are held at the Imperial Hotel, Russell Square, W.C., at 9 p.m., and dinner (5s.) is served at 8. All medical practitioners are welcome.

THE Fellowship of Medicine has arranged daily clinical demonstrations in ophthalmology at the Royal Eye Hospital, Southwark, during the week beginning January 17th, at 3 p.m., and on January 19th Mr. D. C. L. Fitzwilliams will give a special demonstration in the wards at St. Mary's Hospital at 2 p.m. These demonstrations are open to members of the medical profession without fee. At the London Lock Hospital there will be a comprehensive course in venereal diseases from January 31st to February 27th comprising clinical instruction in the out-patient department and formal lectures. A four weeks' course, beginning on January 31st, at the St. John's Hospital for Diseases of the Skin, will consist of instruction in the out-patient department and bi-weekly lectures; classes in pathology can be arranged also. From February 7th to 19th an all-day course in diseases of children will be held jointly by the Paddington Green Children's Hospital and the Victoria Hospital. The Royal Northern Hospital will hold a one-week course for general practitioners, starting February 21st, for which no fee will be charged. The Fellowship can provide for post-graduates practical courses in anaesthetics and in obstetrics, and also arrange for clinical assistantships at the Samaritan Hospital for Women. Copies of all syllabuses and the programme of the general course of work can be obtained from the Secretary of the Fellowship of Medicine, 1, Wimpole Street, W.1.

THE Sims Woodhead series of ten educational health lectures arranged by the People's League of Health will be given in the lecture room of the Medical Society of London, 11, Chandos Street, Cavendish Square, W., on Monday, January 31st, and the following Mondays at 6 p.m. Information regarding the lectures may be had from Miss Olga Nethersole, R.R.C., 12, Stratford Place, W.1.

A NEW course of lectures at the Hospital for Sick Children, Great Ormond Street, W.C.1, was commenced on Thursday last, when Dr. Hugh Thursfield dealt with the treatment of bronchitis and bronchopneumonia. The lectures will be continued on Thursdays at 4 p.m., ending on April 7th, when Dr. Pearson will discuss vomiting in infancy.

THE spring session of the James Mackenzie Institute for Clinical Research, St. Andrews, commences on Tuesday, January 18th, at 4 p.m., when Dr. Maitland Ramsay will deliver a lecture on so-called acute rheumatic iritis. On Tuesday, January 25th, at the same hour, Professor Herring will discuss the physiological aspects of blood pressure. Lectures will be continued on succeeding Tuesdays, terminating on March 29th, when Dr. Fyfe will speak on laboratory observations in acidosis.

THE annual general meeting of the Society of Superintendents of Tuberculosis Institutions will be held at 122, Harley Street, on Monday, January 17th, at 3 p.m. A discussion on the observation case will be opened by Dr. F. R. G. Heaf and Dr. N. Bardswell, and short papers will be read by other members.

As already announced, a conference has been called by the Labour party to consider the present position of nurses. It will be held at the Caxton Hall, Westminster, on January 28th, and will be opened by Mr. Ramsay MacDonald. At the morning session, when Mr. Frederick Roberts, formerly Minister of Pensions, will preside, a discussion on the Sick Nursing Services will be opened by Dr. Somerville Hastings. In the afternoon, when Mrs. Sidney Webb will be in the chair, discussions will take place on nurses employed by the State, to be opened by Mr. George Gibson, General Secretary of the National Asylum Workers' Union, and on public health and preventive services, by Miss A. Sayle, of the Women Sanitary Inspectors' and Health Visitors' Association. Discussion will range round the draft report issued by the Standing Joint Committee of Women's Organizations and the Labour party's Advisory Committee on Public Health, but it is not proposed to adopt specific resolutions or take amendments. The object of the conference is to afford an opportunity for an interchange of opinion, and all suggestions made will receive consideration before the official report is issued. Among the bodies which will send delegates to the conference are the General Nursing Council, the Royal British Nurses' Association, the College of Nursing and Queen Victoria's Jubilee Institute for Nurses, the British Red Cross Society and the Order of St. John of Jerusalem, the National Association of Insurance Committees, and several hospitals in London and the provinces. The British Medical Association has nominated Sir Jenner Verrall, Mr. H. S. Souttar, F.R.C.S., Dr. G. F. Buchan, Dr. Alfred Cox, and Dr. G. C. Anderson to represent it.

THE Gifford Edmonds prize in ophthalmology of £100 is offered for the best essay on the causation and differential diagnosis of proptosis. The award is made every two years, and preference will be given to original work based on any branch of the subject. A notification appears in our advertisement columns, and further particulars may be obtained from the Secretary, Royal London Ophthalmic Hospital, City Road, E.C.

DR. GEORGE CRAN, M.B.E., V.D., was entertained on January 6th by his friends and patients at a complimentary dinner in the Town Hall, Banchory, in recognition of fifty years' zealous professional services in the district, and handsome gifts were presented to him and Mrs. Cran.

DR. A. T. BRAND having resigned the post of medical officer to the Driffield Workhouse, which he has held for forty-three years, the guardians have placed on record their great appreciation of his services.

DR. W. H. ANDREWS, a report of whose recent paper on trypanosomiasis in man and animals appears in our present issue, has been appointed to the post of Director of Veterinary Research in the Ministry of Agriculture's laboratory at Weybridge, in succession to the late Sir Stewart Stockman.

DR. J. C. BRIDGE, one of the medical inspectors of the Factory Department of the Home Office, has been appointed to succeed Sir Thomas Legge as Senior Medical Inspector of Factories.

THE American Society for the Control of Cancer announces that two prizes, each of 50,000 dollars, have been offered by Mr. W. L. Saunders of New York, one for the discovery of the nature and prevention of cancer, and the second for the invention of an absolute cure; the offer is open for three years to medical practitioners or laymen and may be renewable. The terms of the awards will be announced later, and further information may be obtained from Dr. C. N. B. Camac, 76, East 56th Street, New York.

MESSRS. J. AND A. CHURCHILL announce for early publication new editions of Professor A. J. Clark's *Applied Pharmacology*, and of Jameson and Marchant's *Synopsis of Hygiene*.

SINCE September there has been a great increase in scarlet fever in Berlin, the number of cases being almost double what it was in the corresponding period in the previous year, and several schools have had to be closed.

A REPORT on the results of convalescent care of the neuropsychiatric patient, made under the auspices of the Advisory Committee on Convalescence of the Hospital Information Bureau of the United Hospital Fund of New York, has been received. The medical direction of this study was in the hands of Dr. Irving Pardee and Dr. Thomas K. Davis, acting on behalf of the committee on neurological convalescence of the Public Health Committee of the New York Academy of Medicine. Its purpose was to evaluate the customary procedures for the treatment of such cases in convalescent homes, and the hope is expressed that the interpretation of the findings made may lead to better classification and to improvement in the present methods. Among the findings are the marked shortage of beds for neuro-psychiatric convalescent care and the large percentage of patients (35 per cent.) between 20 and 30 years of age.

Letters, Notes, and Answers.

All communications in regard to editorial business should be addressed to ***The EDITOR, British Medical Journal, British Medical Association House, Tavistock Square, W.C.1.***

ORIGINAL ARTICLES and LETTERS forwarded for publication are understood to be offered to the BRITISH MEDICAL JOURNAL alone unless the contrary be stated. Correspondents who wish notice to be taken of their communications should authenticate them with their names, not necessarily for publication.

Authors desiring REPRINTS of their articles published in the BRITISH MEDICAL JOURNAL must communicate with the Financial Secretary and Business Manager, British Medical Association House, Tavistock Square, W.C.1, on receipt of proofs.

All communications with reference to ADVERTISEMENTS, as well as orders for copies of the JOURNAL, should be addressed to the Financial Secretary and Business Manager.

The ***TELEPHONE NUMBERS*** of the British Medical Association and the BRITISH MEDICAL JOURNAL are *MUSEUM 9861, 9862, 9863,* and *9864* (internal exchange, four lines).

The ***TELEGRAPHIC ADDRESSES*** are:

EDITOR of the BRITISH MEDICAL JOURNAL, *Aitiology Westcent, London.*

FINANCIAL SECRETARY AND BUSINESS MANAGER (Advertisements, etc.), *Articulate Westcent, London.*

MEDICAL SECRETARY, *Medisecra Westcent, London.*

The address of the Irish Office of the British Medical Association is 16, South Frederick Street, Dublin (telegrams: *Bacillus, Dublin*; telephone: 4737 Dublin), and of the Scottish Office, 6, Drumsheugh Gardens, Edinburgh (telegrams: *Associate, Edinburgh*; telephone: 4361 Central).

QUERIES AND ANSWERS.

"W. H. F." asks for suggestions for the treatment of persistent cough following acute influenza which has resisted all sedatives.

RHEUMATOID ARTHRITIS.

"M. B." asks for suggestions for the treatment of a lady, aged 60, with rheumatoid arthritis. Having tried other measures without avail, he started to treat her some time ago by intravenous injections of T.A.B. vaccine. The initial dose was 25 million, which he gradually increased by four stages to 100 million, but from the first the reaction was abnormally severe, including violent rigor, pyrexia of 2° to 4°, and a pulse increase to about 140 a minute, but no perspiration. The rigor begins about forty-five minutes after the injection, and lasts for upwards of one hour. The patient becomes slightly cyanosed during it, and when it is over she is quite exhausted and falls into a deep sleep. He has tried reducing the dosage and then increasing it again, but without benefit, the length and severity of the rigor being undiminished. There are no obvious contraindications in the case. "M. B." asks whether in the circumstances it would be advisable to restart the treatment, and would welcome any suggestion for lessening the severity of the reaction.

INCOME TAX.

"COLONIAL" retired from a colonial service and returned to England on December 18th, 1925; on January 10th, 1926, he went abroad and returned in March, 1926. He has been assessed to income tax as a British resident for 1925–26; is this correct?

*** We are of opinion that "Colonial" cannot successfully contest the view taken unless he can show that when he returned to England in December, 1925, he came without the intention of establishing a residence in this country—not necessarily of purchasing or leasing a house, but of making this country his residential headquarters in future. How far he is likely to succeed on those lines must, of course, depend on many circumstances which are within "Colonial's" power to allege and, if necessary, prove.

LETTERS, NOTES, ETC.

HERPES AND VARICELLA.

DR. CYRIL HELM (Great Horkesley, Colchester) writes: On October 5th a man developed typical herpes zoster on the chest. The vesicles dried up, but a fresh eruption occurred on October 20th. On October 25th his daughter, aged 4, developed chicken-pox. The child had not been in contact with any other case. So certain am I that the father infected the child that in future I shall regard every case of herpes zoster as a potential source of infection for chicken-pox.

DR. R. LYNN HEARD (Bexley, Kent) writes: There has lately been a resuscitation of correspondence as to the relation of these two diseases. For a number of years I have had no doubt as to their being merely different manifestations of the same infection. When children have been in contact with persons suffering from herpes (in one case pudendal) I have more than once prophesied that in a fortnight or so the child would develop chicken-pox—which forecast has been verified. I have also met an instance in which chicken-pox in a child was followed by herpes in its grandfather, who resided in the same house.

DR. A. H. SPICER (London, W.) writes: Captain X. Y. noticed a patch of herpes zoster on October 11th. He came to me three days later with a slight but typical rash of varicella, noticed that day. He visited his niece on October 12th or 13th, and she came out with a profuse varicella rash on November 2nd. The patch of herpes was single, and, although the patient was 64 years of age, was quite painless. He apparently infected the niece a day before his varicella rash developed.

HOSPITAL BOARD REFORM IN CAPETOWN.

"SPES BONA" writes with regard to the proposed changes in the constitution of the Cape Hospital Board, to which reference was made in the JOURNAL of September 18th, 1926 (p. 638). He states that the number of persons engaged in the administration of hospitals in the Cape peninsula is much less than the 200 mentioned. He attributes the apparent procrastination and inefficiency of the board to the retention of administrative control by a small number of officials who are ignorant of the hospital needs of the peninsula and conduct hospital affairs without reference to the wishes of the majority of the board. He thinks that the present system of centralization is unworkable, and that the proposal to reduce the number of the board members to eighteen will throw so much work upon them that they will be unable to control effectively the ten hospitals and institutions concerned.

*** While we consider that this subject is more suitable for discussion in the South African medical papers, we think it right to allow this note to follow the previous comment in the JOURNAL. Further discussion, however, should be continued in South Africa, where the facts are more fully known and the matter strictly belongs.

A HOSPITAL ORGANIZER.

PROFESSOR HEINRICH CURSCHMANN left no autobiographical notes which would have served as the basis of a biography, and his sons, in order that such details as it was in their power to collect should not be lost, have published a small volume (Berlin: Springer), written in association with two of his colleagues, who give a brief account of his professional career. The volume pretends to be no more than an outline; to portray so full and active a life within the space of a few dozen pages would be impossible. But his sons have ably performed a pious duty, and the facts amassed will be of value when a full biography comes to be written. The five chapters deal with Curschmann's ancestry and early life in Giessen, Mainz, and Berlin; his work as medical director of the hospital in Hamburg; his professorship in Leipzig; his hobbies in the field of literature and art; and his last years and final illness (Addison's disease). An appendix contains a complete list of his scientific writings, which cover a wide field. His chief studies were in connexion with the infective fevers, the great epidemic of typhoid fever in Hamburg in 1885–86 directing his attention to that subject and affording material for observations in the disease, which became his main interest to the end of his life. Mention should also be made of his work on aortic sclerosis, pericardial effusion, and arthritis deformans; and in this country his name is generally associated with the so-called Curschmann's spirals. In his own country the work for which he is chiefly renowned is, probably, the founding of the Eppendorf Hospital in Hamburg. When he was appointed director of the general hospital in that city it early became evident to him that the accommodation was insufficient for the number of patients. He strenuously opposed suggestions for the extension of the old hospital, and projected a scheme for a large new hospital beyond the suburbs of the city. Conditions became intolerable during the typhoid epidemic; not only were the wards overcrowded, but it became necessary to convert the corridors and even the cellars of the old building into wards. The plan of the new hospital, with its 1,100 beds, was Curschmann's own conception, and was carried almost to completion under his own eyes in daily inspections during the progress of the work. This was an undertaking that exactly suited Curschmann's genius; he was a born organizer, as had already been proved in his management of the old hospital. The new Eppendorf Hospital was scarcely completed when Curschmann received an offer of the post of professor of medicine in Leipzig. This he accepted, but although it had always been his ambition to become an academic teacher, he missed in the new post his old work of organization, and always looked back on the Hamburg days as the happiest in his life. However, he was able to introduce improvements in the hygienic arrangements of the hospital in Leipzig, and it was due to him that the clinical library, with its fine series of medical journals, was brought into the foremost place among the libraries of Germany. The chapter on art and poetry (Curschmann was himself a skilful draughtsman) brings out the sentimental side of the German character, and completes the sketch of a very vigorous and interesting personality.

THE Automobile Association announces that it has opened an office at 11, The Avenue, Southampton; the small office at the docks will be retained. A new A.A. office has been opened also at 10, Middle Row, Maidstone.

VACANCIES.

NOTIFICATIONS of offices vacant in universities, medical colleges, and of vacant resident and other appointments at hospitals, will be found at pages 43, 46, 47, and 48 of our advertisement columns, and advertisements as to partnerships, assistantships, and locumtenencies at pages 44 and 45.

A short summary of vacant posts notified in the advertisement columns appears in the *Supplement* at page 23.

SOME APPLICATIONS OF PHYSIOLOGY TO MEDICINE.

IV.—HIGH BLOOD PRESSURE FROM THE PHYSIOLOGICAL ASPECT.*

BY

J. A. MacWILLIAM, M.D., F.R.S.,

REGIUS PROFESSOR OF PHYSIOLOGY, UNIVERSITY OF ABERDEEN.

(From the Physiological Laboratory.)

IT need hardly be said that the problem of the causation and mechanism of persistent high blood pressure has proved one of exceptional complexity and difficulty. High pressure is a condition or symptom, like pyrexia, probably of different types and modes of causation.

Methods of Estimation.

As regards the measurement of the pressure a combination of the auscultatory and tactile methods is by far the best—very superior as regards accuracy and convenience to various oscillatory and other methods that have been proposed. It may be taken that the readings obtained are in the vast majority of cases an approximately correct estimate of the pressures actually present within the artery. In a very limited number of cases with thickened *contracted* arteries local resistance to compression in the arterial wall may lead to an over-estimation of the intra-arterial pressure, an error that can be obviated by the method of repeated or continued armlet compression. But it is to be noted that in a certain number of cases the method of repeated compression may in turn introduce sources of fallacy if the auscultatory method, *per se* is used. For in some individuals compression, repeated a number of times or kept on for some time, may cause serious disturbance in the auscultatory indices—for example, the systolic reading may come to be much too low, while the diastolic reading becomes too high. The error is detected by combination with the tactile method; the tactile systolic index is now found to be considerably higher than the auscultatory systolic, the pulse beat being easily felt at the wrist long before the armlet compression has been reduced sufficiently to allow the sound constituting the auscultatory systolic index to be recognized. This is one of the instances which illustrate the necessity of checking the auscultatory systolic index by the tactile method—recommended as a routine procedure by Professor Spencer Melvin and myself[23] many years ago. The source of fallacy in question is in my experience seldom, if ever, of importance in high-pressure cases, so the matter need not be further pursued in the present connexion.

Systolic and Diastolic Pressure Levels.

Since Melvin and Murray[27] stated the systolic and diastolic pressure levels in young adults in 1914, evidence on a large scale has become available as to the "normal" pressures in healthy persons—systolic readings 110 to 125 mm. being most common (sitting position), while the value may sometimes be as low as 100 to 105 mm. in subjects in good training, or may be as high as 130 to 140 mm. in some young persons in good health, there being evidently a setting of the normal pressure at different heights. The diastolic level in young adults is usually between 60 and 80 mm.; the pulse pressure has ordinarily a value of 40 to 45 mm.

The relation of age to the pressure values is a matter on which much evidence has accumulated in recent times, thanks largely to the American insurance statistics (Symonds,[40] Rogers and Hunter,[35] MacKenzie,[21] and others), in which records from hundreds of thousands of individuals are available; also to the work of Stocks and Karn[38] in this country. The results led to a correction of a current idea as to there being an extensive rise of pressure in normal persons as life advances and as body weight increases. It is true that there is a very appreciable rise in the later half of life, but this is much more limited than has been currently believed by clinicians, dealing with persons who come under their observation for some ailment or other. Thus the average systolic pressure, in the enormous numbers examined, has been found to show only a comparatively small increase, whatever may be the significance of the much higher pressures recognized in some individuals who enjoy good health.

When the averages of very large numbers are dealt with, it is evident the rising pressure of childhood undergoes some acceleration about puberty and reaches the normal adult level somewhere in the age period of 17 to 20; there is some evidence of a slight subsequent lowering in the early adult years. The pressure then alters little up to the age of about 40, after which a more definite progressive rise becomes manifest. But the actual increase under the combined influences of age and the usually associated increase of weight is on an average under 15 mm., in some statistics much less.

The statistics bear strong testimony to the relative constancy of systolic pressures at different ages, when estimated with the necessary allowances and corrections; they make clear that exceptionally high pressures in healthy persons must be very infrequent, otherwise the averages would be much higher. It is noteworthy that the statistics have largely been obtained in America, with its stress and hurry of life. The importance of hereditary influences or familial tendencies is marked in regard to the occurrence of unusually high pressures, and the association of high pressures with obesity is a notable one, though by no means invariable. At all ages persons of heavy build have higher average systolic pressures (for example, 10 mm., etc.) than persons of light build.

The importance of the diastolic pressure reading and the consequent obtaining of the pulse pressure value need hardly be emphasized. Diastolic pressure represents the resistance against which the contracting left ventricle has to force open the aortic valves, and it represents the constant stress which the arterial walls have to stand. Its importance with regard to the bursting of a weakened artery is great, more than the transient systolic rise caused by each heart beat. This is illustrated by the comparative rarity of cerebral haemorrhage in cases of aortic regurgitation, with its high systolic but low diastolic pressures. Systolic pressure taken by itself may give very defective and misleading indications, for the systolic readings may be at the same level in profoundly different conditions of the circulation.

The diastolic pressures afford data valuable for interpretation of the condition present. Normal or supernormal systolic pressure taken by itself does not necessarily indicate efficiency as regards the mass movement of the blood in the circulation.

Modes of Death in Subjects of High Pressure.

Taking the average results of very large numbers as regards health and duration of life, it is clear that the dice are loaded against the subjects of high pressures, though of course there are many individual examples of long life and activity under those conditions.

In excessively high pressures the fatal ending seems to come by cerebral haemorrhage in about 20 per cent., changes having supervened in cerebral vessels by this time. The not infrequent occurrence of cerebral haemorrhage (like pulmonary and gastro-intestinal haemorrhages) during sleep was long a puzzling phenomenon in view of the accepted conclusion that the blood pressure is lowered during sleep. Why should the haemorrhage take place during a period of reduced pressure? Observations by the present writer[22] on the remarkable rise of pressure that may be associated with disturbed sleep, exciting dreams of motor effort, nightmares, etc., afford an explanation. In contrast with the definite lowering of pressure attending on sound sleep, the steep rise during disturbed sleep may reach an elevation attained in the same individual in the waking state only during vigorous or even violent muscular exertion—for example, systolic pressure rises to 182 and 200 mm. from normal levels of 125 to 130 mm.

[3446]

* Read at the James Mackenzie Institute for Clinical Research, St. Andrews, October, 1926. Previous articles of this series were published in the BRITISH MEDICAL JOURNAL, 1923, vol. i, p. 51; vol. ii, pp. 215, 278, and 1196.

respectively, while diastolic pressure rises from 75 to 105 mm., etc.

It is significant that an American observer (Krumbhaar[20]) has recently found that a relatively large number of ruptures of the heart occur during sleep. In about 50 per cent. of high-pressure cases death is ascribed to cardiac failure. Of course the work of the heart is greatly augmented by the excessive resistance against which it has to pump out its contents. But the reserve power of the healthy cardiac muscle, as Sir James Mackenzie repeatedly emphasized, is very great; the heart is an organ of phenomenal power and endurance, granted a good supply of normal blood to its walls. What usually happens is not simply the wearing out of such a heart by excessive work, but the defeat of a labouring heart impaired by defective nutrition due to lesions of the coronary circulation, and deficient quality of blood resulting from damaged kidneys and other organs. The remaining proportion of deaths has been attributed mainly to uraemic conditions, but are really complex in causation in presence of widespread derangements of function in the later stages.

Interpretation of High Pressures.

The phenomenon of persistent elevation of the arterial pressure may be regarded from different standpoints and given quite different interpretations. It may be looked on as a result of irritative and deranging influences (circulatory toxins or other causes) frequently leading to the development of symptoms of ill health, increasing the work of the heart and tending to cardiac failure, stressing the vascular walls, promoting their degeneration and predisposing to cerebral haemorrhage, kidney changes, etc.

From another point of view the high pressure may be looked on as essentially a compensatory process, while attended in the long run by certain unfavourable effects on the heart and blood vessels. The raised pressure is regarded as compensatory in the sense of its maintaining the circulation or driving more blood through some vital organ that requires it—for instance, the brain, kidney, heart muscle, etc.—either when the flow has been subnormal or when a higher pressure and more rapid flow would be useful in view of functional or structural defects in the tissue.

Janeway[17] concluded that in some persons an average pressure far above the normal is necessary to ensure the requisite capillary blood flow, the optimum arterial pressure sometimes being 200 mm. or more, instead of 100 to 145 mm. Oliver[22] remarks: "We are apt to forget that high arterial pressure is not infrequently a necessary evil and should sometimes be regarded as one of the natural defences of the body." Herringham,[16] referring to certain high-pressure cases, says: "I make little doubt that a high blood pressure is necessary for the life of these patients."

Clifford Allbutt[1] wrote long ago: "High pressure is an attempt of the organism to maintain the equilibrium of the circulation." In his last work[2] he remarks: "The truth is that as high pressures creep on stealthily, the system as silently adapts itself to them; so that blindly to try to reduce excessive pressures permanently to the normal would be as harmful in practice as fallacious in reason." While advising gradual reduction towards the level suitable for the particular individual, he severely criticizes the teaching, based on the belief that high pressure is compensatory, that treatment should not be applied to high pressures: "If an ergot-like poison were crimping up one's arteriolar system or directly irritating the vasomotor centre, would one decline to relax the system for fear of destroying compensation? Certainly not."

While it is well known that a lowering of pressure is sometimes attended by unfavourable symptoms, this does not necessarily prove that the elevated pressure had primarily been compensatory. The rise may have been due to irritative morbid influences in presence of which habituation or adjustment had at length developed, a new pressure level being established. Later, if a fall occurs, readjustment at this phase may not be practicable, especially in presence of failing heart action with defective regulating mechanisms and probably deterioration in kidney efficiency, structural lesions, etc.

It is obvious that with declining heart power relaxation of the arterioles by vaso-dilator drugs would naturally produce unfavourable results, since the physiological mechanism which tends to keep up the aortic pressure by vaso-constriction in presence of defective cardiac output would be upset. But such considerations do not establish the beneficial or compensatory nature of high pressures while the heart is efficient.

It was long ago suggested that high blood pressure might be useful, as far as the kidney is concerned, when there is an excess of material of some sort to be excreted or when the functional power of the organ is defective from structural or other causes. A recent paper from this laboratory by C. Reid,[24] dealing with a mixed series of high pressures, some with and some without renal involvement, yields evidence that does not support the idea of a compensatory function with regard to renal function. Substantial lowering (20 to 60 mm., etc.) of pressure by drugs of the nitrite series or by venesection did not impair the power of the kidney to concentrate urea or diminish the total urea excretion in the vast majority of cases; the urea and non-protein nitrogen of the blood were not increased during the periods of reduced pressure—there was no accumulation of these bodies in the blood to indicate defective excretion. *Evidently renal function was well maintained, so far as* urea and non-protein nitrogen are concerned. Some clinical observations as regards phenolsulphonephthalein by Gruber, Shackelford, and Ecklund,[11] and on guanidine by Major,[21] afford similar indications; the excretion of these substances in the urine was not lessened during periods of lowered pressure.

Causation of High Pressures.

It is hardly necessary to recall the various influences that have been invoked to account for the development of high pressures: (1) nervous, (2) endocrine, (3) toxic, and (4) renal.

While it is obvious that some powerful agency is at work, the search for definite pressor bodies (from any source) in the circulation has proved to be singularly inconclusive. Clifford Allbutt said: "Such catch phrases as intestinal toxins, kidney inadequacy, endocrine disorder, and the like are but dust in our eyes."

Mechanism of High Pressures.

Ideas as to the relations of high pressure and the frequently associated arterial sclerosis have varied much. The old view of von Basch regarded sclerosis as the cause of the high pressure, while the later one of Huchard made the high pressure primary and the sclerosis secondary. At the present time it is accepted that there are two distinct conditions; there may be sclerosis without high pressure at any stage, and high pressure without sclerosis, though persistent high pressure favours the development of sclerosis.

Studies on the viscosity of the blood in high-pressure conditions have not provided any explanation applicable on a wide scale, though a limited group of high-pressure cases associated with polycythaemia and augmented viscosity has been recognized. In the absence of a great increase in blood viscosity or of blood volume (conjoined with ineffectiveness of the normal mechanism of accommodation of such increased volume) it is evident that high pressure must depend on excessive frictional resistance or diminished capacity of the vascular system, or a combination of these factors. The factor commonly accepted as the main one is increased peripheral resistance — increased frictional resistance to the onward movement of the blood from the arteries, dependent on narrowing of the outlet by active contraction of the arterioles or by structural change.

In view of the work of Krogh, Lewis, Dale, and others, which has emphasized the independent powers and strong contractility of the capillaries, the question naturally arises as to the part which these may play in determining excessive resistance in high-pressure conditions, as distinguished from the normal state in which the capillary resistance seems to be slight. Some observations on capillary pressures on the skin, made by modern methods, are described (Boas and Frant[8]) as showing the presence of excessively high values in some types of high arterial pressure, in contrast to cases of simple high pressure (hyper-

piesia, primary or essential hypertension, etc.); this suggests the possible existence of two categories of high arterial pressure, one with and the other without high capillary pressures.

It is to be remarked, with reference to the numerous studies of capillary pressures that have been made by different observers, that measurements of capillary pressure in the skin afford no valid evidence as to the average pressure in the capillary system as a whole, or as to the fric-tion in the total capillary bed. For the capillary pressures in the skin (finger, etc.) are profoundly influenced by local conditions of arterial tone, with the result that the digital capillary pressure may rise while the pressure in the brachial artery falls, and vice versa. And the conditions in the skin area and the splanchnic area of the circulation are frequently opposed, as in muscular exercise, etc. There are no means of determining the relations between the pressures in the skin capillaries and in those of internal organs.

It is not warrantable to speak of "capillary pressure" in the same sense as "arterial pressure," for the latter has a definite value practically identical in all the larger arteries, while the former shows diverse and varying pressure values in the multitude of capillary districts. Still, if it should be confirmed that the skin capillary pressures fall into two categories in cases of high arterial pressure, such a differentiation may prove to have clinical signifi-cance.

Apart from the question of capillary resistance playing an important part, it is evident that a diminished *capacity* of the capillary system would have important effects on the circulation. But there are no means of gauging the size of the total capillary bed.

In the healthy person at rest the arterial pressure which is normal for that individual is remarkably constant within narrow limits, apart from ascertainable disturbing con-tions; the regulating nervous mechanism (medullary centres) is very efficient, as shown by there being little or no change in aortic pressure when the peripheral resistance is markedly increased by artificial compression of large arterial trunks like the brachial or femoral. But in the high-pressure subject this regulating mechanism has ceased to be adequate; the pressure remains at an abnormally high level, and is often subject to sudden and extensive variations, sometimes in the absence of any recognizable cause or from slight exciting influences that would have little effect in the normal individual. The normal regu-lating mechanism includes the depressing or inhibitory effect on the vasomotor centre of high blood pressure acting (1) directly on the centre and (2) through afferent impulses from the heart, aorta, sinus caroticus,* etc. In addition, there is the controlling influence of the vagus centre on the cardiac pump, this centre being also influenced directly by the blood pressure in it and reflexly by afferent impulses from the heart, aorta, and sinus caroticus. Additional recent evidence with regard to this mechanism is to be found in experimental inquiries by Anrep and Starling[4] (cross-circulation experiments), Hering,[15] Nash[20] (sinus caroticus), Daly and Verney,[12] The observations of Eyster and Hooker[13] on the influence of afferent impulses from the aorta have recently been corroborated.

Some Occasional Postural Effects in Man.

Recent observations by me have shown that in some persons the sudden assumption of the horizontal posi-tion may cause an abrupt fall of general arterial pressure of variable amount, sometimes associated with a marked though transient attack of giddiness; the latter is probably due to the pressure change, being absent in these subjects when the pressure fall is not very considerable. Evidently what happens is that the increase of blood pressure in the head on lying down flat, due directly to the hydrostatic factor—the difference in the influence of gravity—depresses the vasomotor centre, causing vascular relaxation and a marked fall of aortic pressure, sufficient sometimes to disturb the equilibrating mechanism of the brain. These unusual cases, not subjects of high pressure so far as has been observed, are explicable as depending on an exaggera-tion of the normal depressing or inhibitory action exercised on the vasomotor centre by a local rise of blood pressure. The fall of pressure is not explained by depressed heart action, there being little alteration in the rate of the heat; pronounced vagus slowing is not observed. Here the vagus centre is not made to show enhanced controlling power over the heart by the increase of blood pressure in the head, which is sufficient to produce strong though very temporary depression of the vasomotor centre. Hence an excessive susceptibility of the vasomotor centre is postulated in the subjects showing this reaction. The brief duration of the marked fall of pressure is a point of difference from the experimental results of Anrep and Starling, who found a continued effect on the vasomotor centre from increased blood pressure in the head in their cross-circulation experi-ments. The reaction in man described above is in contrast to the less uncommon occurrence of giddiness on suddenly standing or sitting up from the recumbent posture, asso-ciated with a lowering of the blood pressure in the head from the direct influence of gravity—as well as other possible causes of disturbance of the equilibrating mechanism. In the cases above referred to giddiness did not occur on suddenly standing or sitting up—only on lying down.

Relation of the Medullary Centres to High Pressures.

Increased peripheral resistance, raising the arterial pressure, evidently depends essentially on constriction of the minute vessels, due to the overactivity of the vasomotor centre or to causes acting directly on the vascular tubes. But there is more involved than a simple increase in peri-pheral resistance, however produced; for a rise of pressure from this cause acting alone would, in accordance with Marey's law, induce slowing of the heart by enhancing the controlling action of the vagus centre. But in high-pressure cases this slowing is wanting, the pulse usually being normal in rate or more or less extensively accelerated. Thus in a series of 241 cases Mannaberg[26] found 55 per cent. with normal pulse rates, 43 per cent. with quickened pulses (mostly in women), and only 3 with slow pulses. The high pressure fails to bring out the normal controlling influence of the vagus centre on the heart rate, an indica-tion that alongside of the constricted state of matters in the peripheral vessels there is an altered condition in the medulla, affecting the vagus centre and no doubt the closely related vasomotor centre—overaction of the vaso-motor centre producing excessive general vascular constric-tion, alongside of altered behaviour of the vagus centre. Accepting the conclusion that in high pressures over-activity of the vasomotor centre is caused by pressor agencies, whether nervous or chemical, it is evident that such pressor action may act in two ways: (1) by a direct irritative action on the centre, or (2) indirectly, by impair-ing the blood supply and oxidation in the centre, and thus exciting it to overactivity, as such conditions are known to be very effective in doing.

Starling[27] has suggested a local impairment of this kind as being possibly due to claudication of the vessels supply-ing the centre, or to toxic damage of its capillaries or interference with the oxidative process, and that such may be responsible for certain forms of high pressure. Following upon this suggestion Bordley and Baker[9] have recently re-ported the finding of arterio-sclerosis in the medulla in a number of high-pressure cases, in contrast to the findings in subjects who had had normal pressures. But it remains to be seen whether such sclerotic changes are primary or secondary.

There are various phenomena of high-pressure cases that are difficult of explanation on the hypothesis of limitation by structural causes of the medullary blood supply.

1. The frequently marked effects of continued mental and muscular rest—often involving a lowering, for the time being, of the pressure more extensive than can easily be accounted for by the slowing of the heart and the absence of the pumping movements of the skeletal muscles which promote the venous return to the heart during move-ment, etc.

2. The remarkable lowering of many abnormally high pressures that has been noted during sleep (Brooks and Carroll,[10] Müller,[29] Blume,[7] Katsch and Pansdorf[19]). A

* The "sinus caroticus" is a name applied to the first portion of the internal carotid artery immediately above the bifurcation of the common carotid. It receives afferent fibres from a twig of the glosso-pharyngeal nerve.

notable constancy of pressure levels during sleep (for example, 5 mm. variation during sleep) has been observed, in contrast to the extensive variations often seen in the waking state. Katsch and Pansdorf found an unusual range of reduction during sleep in essential hypertension, in contrast to other forms of hypertension where there was little or no reduction.

3. The occurrence in some cases of extensive variations of pressure from day to day or at shorter intervals (hours) —apparently not accountable for by changes in heart action.

4. The apparently "spontaneous" recoveries from high pressures sometimes seen.

5. The pressure-reducing effects of the ingestion of large amounts of water, to be referred to later (Orr and Innes).

There is obvious difficulty in reconciling such considerations with the idea of a high-pressure mechanism depending on the existence of established structural changes in the vessels of the medulla or the general circulation; they point to a notable variability of resistance, as contrasted with a fixed increased of resistance set up by structural alterations in the vascular circuit. An assumption that such variability of pressures is explicable by changes in the cardiac action is not warranted.

It would appear that the incidence of the pressor influence responsible for high blood pressures is primarily on the central nervous system, not directly on the peripheral vessels as a whole. The disturbance of the medullary regulating mechanism is evidently due either to (1) interference with the normal blood supply to the brain or the medullary portion of it, or (2) the influence on the centres of some abnormal disturbing agent arriving in the blood, or (3) nervous impulses reaching the centres from other parts of the brain or from peripheral structures.

As regards (1) it remains to be seen whether indications may be derived from a study in high-pressure subjects of the behaviour of the respiratory centre, which from its close topographical and functional relations with the vagus and vasomotor centres would naturally be affected by inadequacy of the blood supply to this part of the brain stem.

Suggested Pressor Substances.

Salt, cholesterol, urea, adrenaline, "renin" (from damaged renal tissue), and many other substances have been under trial, and have either been acquitted or given a verdict of "not proven."

There has long been a presumption that protein derivatives—products of incomplete or perverted metabolism or results of microbic action in the alimentary canal or the tissues—are frequently concerned in the genesis of excessively high blood pressures, though a pressor agent in the blood has not been identified or isolated. Experimental investigations (feeding, etc.) on this subject have given conflicting results in recent years. Thus Mosenthal,[28] Squier and Newburgh,[36] Strouse and Kelman,[39] and Anderson[3] report no elevation of pressure from increased protein feeding in high-pressure cases, while some other observers—for example, Nuzum[31] and others among recent workers—have reported different findings. Foster describes a reduction of pressure from long-continued low protein diet, and Benedict a reduction from normal under a diet of low calorie value and low protein content. Again, in a collection of low-pressure cases it has been found that high protein feeders are 28 per cent. less numerous than among normal blood pressures.

Allbutt concluded that there is no evidence of the accumulation of non-protein nitrogen in the blood or default in the urine, that intestinal disorder is incidental, and that there is no proof of the absorption of intestinal poisons to be got from examination of the urine. It is to be remarked that feeding experiments deal more directly with the amount and completeness of protein metabolism rather than with possible perversions of this process in certain types of this subject.

In view of the recognized hereditary liability to the development of high pressures—as strikingly illustrated in many families—under the influence of nervous strain, worry, unfavourable habits of life, dieting, etc., there may well be inborn susceptibility to derangement in the metabolism of proteins and associated substances in these subjects.

Orr and Innes,[22] working in this laboratory, a few year ago made the remarkable observation that ingestion o large amounts of water tend to induce a notable lowerin of elevated blood pressure—a result attributed to the wash ing out of intermediate metabolites, presumably of protei origin. Whatever be the ultimate explanation, th pressure change is often both marked in extent and o much longer duration than is commonly the case with depressor agencies. Reduction from such a pressure a 200 mm. to normal, maintained over many months, has bee effected. Decided results seem to be obtainable in a con siderable proportion of high-pressure subjects. The appli cation of this method is being made the subject of furthe investigation; it is clearly worthy of being given a extended trial. The slight preliminary rise of pressur which may follow the ingestion of large amounts of wate does not seem to have been attended by any unfavourabl results in primary or essential hypertensions.

A pressor agent recently suggested by Major and Stephen son[23] is guanidine—a substance which, on intravenous o intramuscular injection, gives a rapid and extensive elevatio of arterial pressure. The excretion of guanidine was foun to be markedly interfered with in experimental uraniu nephritis (dogs), and in a number of high-pressure patient a diminished output was observed and compared with th normal daily average of about 100 mg. It is suggeste that guanidine, as being somewhat difficult of excretion might be partially retained in developing kidney defec at a phase too early to be recognized by the usual tests. In this connexion it would be interesting to have evidenc as to the blood pressure in tetany—for example, from para thyroid defect, where guanidine has been found in th blood by Noël Paton and his associates; also whether an high-pressure cases are favourably affected by parathyroi feeding and calcium salts. Hyperthyroidism, though some times associated with high blood pressure, is ruled out a a common cause by the results of examination of the basa metabolism.

Relation to Kidney Conditions.

While kidney conditions have long been prominently in question, whether in primary or secondary relations, it i now generally accepted that high pressures frequently occu (hyperpiesia, primary or essential hypertension, etc.) apart from any recognizable lesion or functional defect of the kidneys as examined by modern methods. Still there can be no question that the presence of kidney defect, whether it be primary or secondary, constitutes a formidable handicap on the subject of high pressure and profoundly influences his chances of health and duration of life. This is so, whether the detriment arises through (1) limitation of the excretory function of the organ, leading to the retention of noxious irritant substances in the circulation, or (2) to the entry into the blood of some product of damaged renal tissue—for instance, the "renin" of Tigerstedt and Bergman, suggested as a causal agent by Batty Shaw[5] in some high-pressure cases.

Experimental reduction of the amount of kidney tissue below a certain limit (for example, to one-third) has been shown to lead to a rise of blood pressure; this has been assumed to be due to the action of retained substances (of unknown composition) which ought to have been excreted. The actual presence of such bodies of a pressor nature has not been demonstrated in the blood. In these reduction experiments there is the complication of the possible absorption into the circulation of pressor substances from damaged renal tissue, as indicated by the recent evidence adduced by J. R. Cash[11] in which 50 to 85 per cent. diminution of renal substance was associated with a pronounced rise of arterial pressure.

Relation to Depressor Substances.

Defect of depressor substances in the circulation is evidently one of the conceivable causes, assuming that the normal blood pressure is maintained by the interplay and balance of pressor and depressor influences. As is well known, chemical substances of depressor nature are very widely distributed in the animal tissues, and many observers question whether the substances are mainly of the nature of histamine and choline or are quite separate from these bodies—a question which is in dispute, as shown

by the recent contributions of Vincent and Sheen[41] and others. If high pressure can result from default of depressor substances the failure of the search for separate pressor agents in the blood might conceivably be accounted for.

A tissue extract that has recently been the subject of active investigation is liver extract, which has been found to have pronounced depressor effects, studied by various observers. As prepared by James, Laughton, and Macallum,[18] the active extract is stated to be free from the shock-producing substance histamine and from choline. Fresh extract is necessary, and while the experimental effects are marked, the clinical data in high-pressure cases in man are not conclusive. Major reports striking and lasting effects in certain high pressures of recent origin without recognizable lesions, while not overlooking the occurrence of occasional "spontaneous" recoveries in such cases. In "fixed" pressures of long standing there was little evidence of specific effect with the liver extract. Some observers interpret the depressor effects of the liver extracts which they used as being due to histamine and choline (Best, Dale, Dudley, and Thorpe[6]).

Conclusion.

From the foregoing considerations it is evident that while the incidence of the disturbing agency on the medullary regulating centres is clearly indicated, precise and adequate knowledge of the causation and mechanism of high pressures is defective. The fact of high pressures coming under observation in man only, and the consequent inapplicability of many of the methods of experimental research, have to be borne in mind as limiting the modes of attack upon the problem. While it is obvious that much more knowledge is necessary for the definite solution of the question involved, it has seemed advisable to take stock of the present situation as it appears to a physiologist, in order to avoid the waste of laborious work in accumulating data such as are already available. It is necessary to keep an open mind as to the possibility of a solution being found in an unexpected direction—in the discovery of a precise causal agent or agencies different from those that are mostly in question at the present time as bearing on the condition of high pressures, which may prove to be multiform in causation and mechanism as also in clinical type.

THE INSECT TRANSMISSION OF ONCHOCERCA VOLVULUS (LEUCKART, 1893),

THE CAUSE OF WORM NODULES IN MAN IN AFRICA.*

BY

D. B. BLACKLOCK, M.D., D.P.H.,

PROFESSOR OF TROPICAL DISEASES OF AFRICA, UNIVERSITY OF LIVERPOOL.

AMONG the families of parasitic nematodes which infest man none surpasses in diversity of interest the family Filariidae. This is due both to the pathogenic effects produced by some species, and also to the strange biological adaptations in the human host and in those insect vectors so far known. Complex problems are presented by the larval habits of different species, some living in the blood stream, others having their chief habitat in the skin; some showing the remarkable phenomenon of periodicity, the causes of which are still obscure. No less important are its historical associations; since it was with the species *Filaria bancrofti* of this family that Manson worked when, in 1878, he made the discovery—destined to revolutionize the tropics—of the part played by insects in the transmission of human disease. From this observation dates all that research into the association of insects with disease which has already produced such significant results and which is daily achieving fresh discoveries in the ever-widening domain of human and animal parasitology.

The Genus Onchocerca.

Included in the family *Filariidae* is the genus *Onchocerca* (Diesing, 1841), which has one species, *O. volvulus*, parasitic in man in Africa, another species, *O. caecutiens*—so closely allied with *O. volvulus* that some authorities consider it identical—parasitic in man in Central America, and several species parasitic in domestic and other animals in various parts of the Old and the New World. Naturally the two species which are parasites of man are of great direct importance. They have a restricted geographical distribution, the ill effects produced by them being confined to the limited regions in which they occur. Of a different order, and affecting man much more widely, are the indirect ill effects produced by those species which infest domestic animals, especially cattle.

Onchocerca volvulus (Leuckart, 1893) infests man in tropical Africa with an intensity which varies in different localities. In West Africa there are large areas in which a very high percentage of the total population is infested. Prout (1901) in Sierra Leone was one of the first to describe it. The worms live in nodules in the subcutaneous and deeper tissues, and give rise to larvae which find their way into the skin; an infested area of skin may contain vast numbers of larvae, so much so that not even the smallest portion can be removed without numerous larvae being found. Different observers have attributed to the worm an etiological significance in the production of very diverse pathological effects, which depend on the distribution of the worm itself in the body and of the larvae in the skin. Several forms of skin disease, itch, ulcers, as well as glandular enlargements, hydrocele, and elephantiasis, are some of the conditions with the production of which this worm is credited.

Mode of Transmission of Onchocerca.

The transmitting agents of several of the Filariidae are already known, if we accept invasion of the proboscis as evidence of the insects being capable of transmitting; up to the present time, however, no one has succeeded in demonstrating by what means any species of the genus Onchocerca is transmitted from man to man or from animal to animal. As a result of investigations carried out at intervals during the past four years I believe that I am now in a position to state that the conditions essential to transmission of *O. volvulus* are fulfilled by a biting insect, a species of the genus Simulium, named very appropriately *Simulium damnosum*. These investigations were undertaken in the Konno district of the Sierra Leone

* An address delivered before the Sierra Leone Branch of the British Medical Association.

Protectorate, where the worm is common. More detailed accounts are being communicated to the *Annals of Tropical Medicine and Parasitology*, in which the first experiments were published in February, 1926.

The Konno District.

The Konno district of the Protectorate of Sierra Leone lies to the north of the railway line which traverses the Protectorate from west to east. It is a hilly region drained by several large rivers and a multiplicity of small streams; the hills are in most cases clothed with dense bush right to the summit. Each village has in its immediate vicinity several streams; swampy areas produced by silting up and overflow of the streams are numerous and biting insects are plentiful. The population is largely agricultural, and both sexes spend much time working on farm lands situated in the dense bush; the streams are used for latrine purposes as well as for washing and drinking. The result is a goitrous population and one heavily infected with urinary schistosomiasis; intestinal diseases, helminthic, protozoal, and bacterial, are rife. The following facts concerning the disease caused by *O. volvulus* demonstrate its prevalence and illustrate the kinds of observation made in order to ascertain its pathogenic effects on the population.

The Subcutaneous Nodules.

The character of the subcutaneous nodules produced by *O. volvulus* varies from a smooth, soft, just palpable nodule to a large, irregularly nodular, hard mass of the size of a large walnut. The first type is usually found in the region of the great trochanter, on the ribs, and on the scalp; the second is generally closely associated with joints, more especially the elbow and knee joints; neither type is usually adherent to the skin, but in some cases, especially over the region of the great trochanter, the skin over the nodule is thickened, partly adherent, and polished on the surface from pressure.

Distribution of the Larvae.

The larvae of this species were seldom found by me in the blood, only a rare larva being present occasionally in the blood film, and that probably derived from the infected skin. The larvae are present in the skin, and may often be found there in large numbers, even when no nodules can be discovered. They are not, however, evenly distributed over the body; thus, while of 93 persons whom I examined by making four sections of the skin of each—that is, from the scapular, loin, thigh, and ankle region—over 45 per cent. proved to be infected with *O. volvulus*. The larvae occurred in these sites in the following order of frequency from the highest to the lowest: loin, thigh, scapular region, and ankle.

Diagnosis of Infection.

The presence of the worm in the body may be detected either by puncture of the nodules and the discovery of the larvae in the aspirated fluid, or by cutting off with a razor small pieces of the skin, which are then teased with strong needles in a drop of water, so as to liberate the active larvae; apparently the first discovery of microfilariae in the skin of man by this latter method was made by O'Neill in 1875 on the Gold Coast. The larvae, although they do not live in the blood, have nevertheless to be distinguished from those of *F. bancrofti*, *L. loa*, *A. perstans*, and also from *Ag. streptocerca*, the last named being a skin microfilaria described by Macfie and Corson (1922). It was found in the Konno district that only 40 per cent. of those who had *O. volvulus* larvae in the skin had also subcutaneous nodules, while of those in whose skin larvae could not be found 16 per cent. had nodules. The examination of skin gave, therefore, a higher percentage of positive findings, and it has the advantage of being easier to carry out in natives than puncture of the nodules.

Pathogenic Effects of the Worm.

In view of the fact that many observers have recorded severe lesions of the skin, glands, and, in the case of the American human Onchocerca, of the eyes, it was advisable to ascertain whether similar effects would be found in Sierra Leone.

The Eyes.—Sixty-one cases in whom the eyes were examined and the skin was searched for larvae yielded 29 instances of *O. volvulus* infection. Only 6 of the 61 had any abnormal condition of the eyes and only 4 of these 6 belonged to the infected group. The eye conditions pterygium, blepharitis, and defect of vision were not associated with the presence of nodules in the head, and the last named appeared to be rather associated with advancing years than with the infection with *O. volvulus*. The examination revealed the fact that in the Konno population the eyes did not suffer notably from either toxic or other effects produced by the worm.

The Skin.—In an examination of 60 people 17 were found whose skin displayed no trace of disease visible to the unaided eye. This absence of obvious skin disease did not, however, prove to mean that none of these 17 cases was infected; for in point of fact no fewer than 8 of them were proved to be infected with *O. volvulus* by the discovery of its larvae in the skin. It was thought that the age of the person might have some bearing on the question, on the assumption that skin disease as a result of infestation might be a transitory condition on the one hand or a late developing one on the other. Against this, however, was the fact that the youngest case showing larvae in a good skin was 24 years of age, while the oldest was 51. The conclusion reached was that infection with *O. volvulus* does not necessarily connote obvious disease of the skin, although it may often coexist with it.

The Glands.—In 68 cases the glands were examined, and it was found that of those having *O. volvulus* larvae in the skin only 27 per cent. had enlarged glands, while of those not having larvae in the skin 32 per cent. had enlarged glands. Admitting that such skin examination as described must inevitably fail to reveal more than a fair percentage of cases, it may be said that on the whole this investigation did not yield definite evidence of pathogenic effects on the glands.

Thus neither in the case of the eyes, the skin, nor the glands did this Konno population show pathological effects definitely and solely attributable to *O. volvulus* infection. It is nevertheless probable that in localities where hyper-infection with the worm occurs a different clinical picture may be produced; very suggestive of this is the work of Ouzilleau (1913), who ascribes to the agency of *O. volvulus* lymphatic gland enlargement, hydrocele, and elephantiasis, occurring in a region in the Congo where *F. bancrofti* could not be found while *O. volvulus* was common. Dyce Sharp (1926), who has made a study of onchocerciasis in Nigeria, observes that the larvae of *O. volvulus* occur with great frequency in hydrocele fluid, and that, while possibly innocuous, they may well stand in some causal relationship to this condition as well as to elephantiasis.

Experiments to Discover the Transmitting Agent.

The investigation of the problem of transmission was begun in 1923-24 and continued in 1925 and 1926. The question was approached from the view that, as the larvae occur not in the blood but in the skin, any blood-sucking arthropod to be capable of transmitting it would have to damage the skin and dislodge the larvae in its efforts to reach blood. The Congo floor maggot *Auchmeromyia luteola*, common in Konno houses, seemed a possible agent in so far as producing damage to the skin is concerned, and specimens of this were first dissected, but no larvae were found. At several villages in December, 1923, and January, 1924, it was observed that *Simulium damnosum* Theob. was biting viciously and in great numbers beside the streams; it was noticed that although this species attacked the skin readily it was slow in reaching the blood and appeared to have difficulty in getting through the skin; this delay led to the belief that, in biting, this insect inflicted considerable damage on the skin, a belief which was strengthened by an examination of the biting apparatus of the fly. One hundred specimens captured were examined for larvae in the gut, but nothing was found, and owing to pressure of other work the search was abandoned temporarily.

Discovery of O. volvulus Larvae in the Gut of Simulium damnosum.

In 1925 at another village the search was resumed, and this time with success; infection of the gut with larvae morphologically identical with those of *O. volvulus* was discovered in 20 out of 780 flies—that is, in 2.6 per cent.—captured on unselected boys. Two men known to be infected with larvae of *O. volvulus* in the skin and in whom no other microfilariae could be detected were then submitted to the bites of the flies; as a result the percentage of gut infection in the fly rose at once to 17. The most heavily infected person was then submitted alone to the flies, the following regions being exposed to them in successive experiments: the loins and upwards gave 28 per cent. of gut infections; the waist and hips only gave 59 per cent. of gut infections; finally the person was exposed so that the flies could bite only on a four-inch-wide band of skin round the body, having the nodules, which were present near each trochanter, in the centre of the band; this experiment gave a positive gut infection in the flies of 80 per cent.

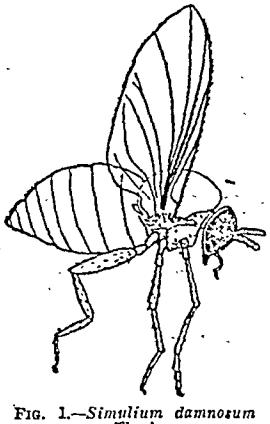

FIG. 1.—*Simulium damnosum* Theob.

Development in the Thorax of Simulium damnosum.

During the dissection of the thorax of 1,320 wild Simulium caught on unselected boys 15, or 1.1 per cent., were found to have developmental forms of some nematode larva present in the muscles of the thorax. Extensive examinations of samples of the population and of animals and a study of the biting habits of the fly led to the exclusion of other members of Filariidae and to the conclusion that the thoracic forms found were in all probability derived from *O. volvulus*. Flies fed on selected cases as described above were kept alive as long as possible and the thorax dissected; the effect was seen in a progressive rise of the percentage of thorax infection, first to 10 per cent., then to 32 per cent., and finally, in flies fed on the four-inch band in the heavily infected case, to the high figure of 82 per cent. No development actually into the head was observed in the course of these experiments, although one form was found partly embedded in the posterior part of the head. It was therefore impossible to make any definite statement at this time beyond recording the fact that the larvae of *O. volvulus* are readily ingested by *S. damnosum*, and that development up to a certain stage occurs in the gut and thorax of this blood-sucking insect.

Development of O. volvulus in the Head of Simulium damnosum.

In 1926 a further series of experiments was carried out and evidence was obtained that the development in the thorax continues with progressive increase in size and morphological modification till the larvae, having invaded the head region of Simulium, finally reach the proboscis. They enter the labium of the fly, where they remain coiled up and ready to emerge, which they do at once when provided with favourable conditions. The experiments are too numerous and long to give in detail here, but they may be summarized briefly as follows:

In six experiments 502 flies were allowed to feed freely on the heavily infected case referred to above; of this total 201 were dissected at a period later than the third day, and in the thorax of 127 of them (63 per cent.) developmental forms were discovered; in the head developmental forms were found in 34 (16 per cent.). The earliest infection of the posterior part of the head was five days, and of the anterior part of the head seven days, after the infecting feed. The development of *O. volvulus* in the fly from the time it is taken up from the skin until it reaches the labium and is mature and presumably capable of infecting a human being occupies about ten days. During this time the larva has undergone great changes in form; not only so, it has also increased in size from about 250μ long by 7μ broad to over 760μ long by 20μ broad.

Summary of Development in the Fly.

The skin forms taken into the gut of Simulium accumulate at the margin of the blood coagulum lying between this and the gut wall. They are very active and the majority pass out of the gut within twenty-four hours and may be found in the posterior part of the thoracic muscles in forty-eight hours. They have altered completely in shape, having increased in width and acquired a characteristic caudal spine-like appendage which may be either straight or much curved; they have also lost a great deal of their mobility. Several moults appear to occur before the form is reached which is capable of invading the head. The advanced thoracic forms show progressive stages of development of the alimentary canal, which is differentiated first into anterior and posterior portions, of different calibre and separated from each other; these unite later to form the uniform gut of the proboscis form, which runs from the head to open in a slit-like anus in front of the tail.

The Effect of Temperature on Development.

Differences in the rate of development were noted at different temperatures. It became evident that, although almost identical percentages of flies had acquired infection at the higher and lower temperatures used, the lower temperature had a retarding influence on development to such an extent that the flies usually died before the head became infected. Thus of 78 flies which lived for six days or over and were dissected, the absolute maximum temperature being 88° F., the absolute minimum 49°, and the average minimum 58°, only 5—that is, 6 per cent.—became infected in the head. Better results as regards head infection were obtained with an absolute maximum temperature of 87°, an absolute minimum of 63°, and an average minimum of 68°. In these circumstances, of 52 flies which lived six days or over and were dissected, 16—that is, 31 per cent.—were found infected in the head.

Le., Labrum-epipharynx. H., Hypopharynx. M., Mandible. Mx., Maxilla. Mx.P., Maxillary palp.

Ovarian and Parasitic Development.

In flies allowed to feed on severely infected skin and then kept in tubes a heavy mortality ensued. Part of this appears to be due to the large number of worms developing in the fly's tissues; part was attributable to the ill effects of retention of the ova owing to the experimental conditions not being suitable for oviposition. Low temperature retarded the development of the ovaries as well as of the

parasites, and the two processes presented a definite correspondence in developmental rate. A correspondence of this kind is to be expected if the fly, after ovipositing, is to be capable of infecting at the next time of biting.

Emergence of Larvae from the Head of Simulium damnosum.

When the larvae had taken up their final position in the labium and were fully developed they were observed to emerge spontaneously into a drop of monkey serum which had been warmed; this phenomenon evidently depends on a definite attraction exercised by such serum, because a drop of warmed normal saline solution did not produce the same stimulating effect on them. Apart from such spontaneous emergence the larvae were seen to emerge when very light pressure was applied to the head region with a needle.

Experimental Inoculations into Animals.

Two monkeys were inoculated intra- and sub-cutaneously, the first in the flank and the second in the head, with advanced forms of larvae contained in the heads of flies. Neither of the monkeys showed any immediate reaction, the incisions healing by first intention, nor has any development so far become apparent. As, however, only two months have elapsed since the first animal was inoculated it is too early to express any opinion as to the ultimate result.

The Habits of Simulium damnosum.

Simulium damnosum Theob. in the Konno district is a small stout fly about 3 mm. long, almost black, and of inconspicuous appearance. It belongs to the same group of flies as those which are sometimes called Buffalo gnats, Turkey gnats, and black flies, and is common in many parts of equatorial Africa. It occurs in Uganda, where it is known as Mbwa, and in the Sudan, where it is called Kilteb; in the Konno it is called Mooli, and in Lokkoh, Poondee gootena = short mosquito. It is a notoriously vicious biter and is much dreaded in regions where it is numerous. The fly is to be found in the bush and grass in the vicinity of water; collectors always went to the waterside in order to find it easily. It dislikes strong sunlight and heavy rain; it likes shade and humidity; a great deal of its movement is by crawling and hopping, rather in the manner of a flea. In tubes it moves towards the light, a fact which can be made use of in changing flies from one tube to another. Only the female was found biting, and the biting habit is diurnal. It proved unwilling to come out far in strong sunlight to feed; it preferred to feed, if situated in fairly open country, during the hours when the sun was not strong, the early morning and late in the afternoon. It makes no sound and bites most frequently low down on the body, from the waist downwards, choosing especially shaded portions of the legs. The presence of overhead shade gives it an opportunity of biting higher up on the body. Palm-tree climbers state that it bites them in the dense palm bush even when they are far above the ground. The fly takes from one and a half to five minutes to engorge; when it has fed it looks remarkably distended, and is so heavy that it flies with difficulty. It was not found to follow man for any distance, and it is not a fly which attracts the attention by flying round the face. One may, in fact, walk along a path without seeing a single fly, although in the grass a yard or two away there may be dozens of them concealed. For this reason many Europeans who pass from rest house to rest house, and do not frequent the streams and marshy areas, may be entirely unaware of the presence of this noxious insect.

With this brief account of the habits of *Simulium damnosum* we may conclude the section dealing with *O. volvulus*. From the experiments recorded it appears extremely probable that this worm is transmitted from man to man by the bite of *Simulium damnosum*. At the same time it must be stated that the only unequivocal evidence will be that furnished by recovery of adult worms from animals or man infested by larvae which have developed in laboratory-bred flies as a result of feeding upon *O. volvulus* infested human beings. Such evidence I regret that I am not in a position to place before you, as up to the present time I have not been able to obtain laboratory-bred flies.

We may now pass on to consider very shortly two other species of the genus Onchocerca—namely, the American human parasite *Onchocerca caecutiens*, and a parasite of domestic cattle, *Onchocerca gibsoni*.

Onchocerca caecutiens.

This species was erected by Brumpt not so much on morphological as on biological grounds; it is a parasite of man in certain parts of Central America, and produces in man worm nodules which occur almost exclusively on the head. Brumpt (1919) named this species *caecutiens* ("blinding") because of the very remarkable account given by Robles in Guatemala of the severe eye symptoms and lesions which are associated with its presence, and which disappear with dramatic suddenness after removal of the nodules from the head. Robles (1919) records several instances in which the nodules formed by this species had eroded right through the cranial vault and were lying directly upon the meninges. On epidemiological grounds Robles several years ago suggested that two species of Simulium locally called "coffee flies"—that is, *S. dinelli* and *S. samboni*—were possibly the transmitting agents of this worm.

This American species is considered by some to be morphologically identical with the African one which has been discussed above. One of the points upon which Brumpt lays stress in the differential diagnosis of the two species is that the nodules caused by the American species are situated in the head in 99 per cent. of cases, whereas the African species causes nodules which in only 1 per cent. of cases are situated in the head. I may record here the fact that in one village in the Konno district I recently found that many of those who had nodules had them in the head. In a population of 66 examined, 33 (50 per cent.) presented nodules in some region of the body. Of the 33 who had nodules, 8 (24 per cent.) had them on the head, the diagnosis being made by puncture. On searching for an explanation for this unusual incidence two points were noted which appeared suggestive. The first was that this little village of eleven houses occupied less space than any other village of the same number of houses seen by me; the houses were arranged in a close ring practically touching each other. The second fact was that the village was shaded by large trees, as was also the path down to the river beside which the village was situated. In such a place as this it was possible for *Simulium damnosum* to attack the upper parts of the body without exposing itself to the sunlight. I concluded that it might be because of the local conditions as regards high shade that so many persons in this village presented nodules on the head. From inquiries which I have made from persons familiar with the conditions on the coffee plantation in Guatemala it appears that coffee in that country is most commonly grown under overhead shade. This fact might partly explain the incidence of the nodules of this species in the head, more especially if the lower parts of the body are covered by trousers and some kind of footwear.

Onchocerca gibsoni.

Of the numerous species of Onchocerca affecting domestic animals that which produces effects most similar to those of *O. volvulus* is *O. gibsoni* Cleland and Johnson, 1910. This species is a parasite of cattle; it produces worm nodules which damage the meat and render it unsaleable. Australia is one of the greatest sufferers from the effects of this species, and its presence in cattle entails a very heavy annual loss. Gilruth and Sweet (1911) state that no cattle station in Queensland is entirely free from the parasite, and that on some stations the infection amounts to 100 per cent. The worms live in nodules of varying size, some of them being subcutaneous and palpable or even visible, while others are situated deep in the intermuscular planes, in the connective tissue. They occur in such numbers in many cases that, although there is no evidence that either infection or injury to the health of man could result from consumption of meat containing

them, a carcass is rendered so unsightly by them that it is unfit for use. This has in the past led to the condemnation of such infected carcasses at the ports of London and Liverpool. It has been estimated (Commonwealth of Australia, 1917) that the discovery of the source of infection with worm nodules may eventually save Queensland over £1,000,000 a year if the grazier is aided in preventing infection.

Very little experimental work appears to have been done in Australia with any species of Simulium in connexion with the genus Onchocerca, although very numerous unsuccessful experiments are recorded with the larger biting insects such as tabanids. Yet Simulium is by no means unrepresented in Australia, several species having been described, one of which is suggestively named *furiosum*. Lea (1917) records a species of Simulium very abundant in the south-eastern parts of South Australia, occurring in thousands and causing series annoyance to horses and cattle. In view of the results obtained with *Simulium damnosum* and *O. volvulus* I would suggest that a species of Simulium may prove to be the carrier of *O. gibsoni* in Australia, or at least that this work on *O. volvulus* points to the desirability of carrying out a series of similar experiments with various species of Simulium and *Onchocerca gibsoni* in Australia.

ANALYSIS OF A SERIES OF CASES OF CARDIO-VASCULAR SYPHILIS.

BY

H. L. HEIMANN, B.A., M.D., M.R.C.P.,

HONORARY ASSISTANT PHYSICIAN, JOHANNESBURG GENERAL HOSPITAL; LATE RESIDENT MEDICAL OFFICER, NATIONAL HOSPITAL FOR DISEASES OF THE HEART, LONDON.

THIS article deals with 105 cases of cardio-vascular syphilis among in-patients of the National Hospital for Diseases of the Heart, London, during the years 1919 to 1923 inclusive. An inquiry was sent to each patient so as to ascertain, as far as possible, his subsequent history, and, where practicable, the patients were re-examined in June, 1923, on which date 21 cases could not be traced. All the patients had positive Wassermann reactions in the blood serum. The series includes three patients each with a history of acute rheumatism, none of whom had mitral stenosis. One case terminated in an infective endocarditis. The symptomatology and course of these cases were not unlike the others, and they have not been excluded. The youngest patient was aged 22, the oldest, 71, the average age being 48 years. There were 97 males and 8 females—an approximate proportion of ten to one. Of the 105 patients, 31 had a history of chancre, and the average time between infection and admission to hospital was twenty-four and a half years.

Cardio-vascular syphilis in the first twenty years of its course is a latent disease; once it manifests its symptomatology its progress is rapid, as is indicated in dealing with the mortality. Valvular involvement in the form of aortic regurgitation occurred in 81 patients; no organic valvular lesion was found in the remaining 24. The critical symptoms, single or multiple, were as follows: shortness of breath, 55 cases; pain (cardiac), 44; giddiness, 17; palpitation, 16; fainting attacks, 11; cough, 4; haemoptysis, 1; swelling of legs, 1.

The relation of these symptoms and signs to the presence or absence of valvular lesions may be tabulated as follows.

Signs and Symptoms in 105 Cases of Cardio-vascular Syphilis: Group I, with Regurgitation; Group II, with no Valvular Lesion.

(The percentages are of the respective groups, not of the total cases.)

Signs and Symptoms.	Group I (81 Cases).		Group II (24 Cases).	
	No.	Per cent.	No.	Per cent.
Dizziness and giddiness	34	42	13	54
Faintness	4	5	3	12
Shortness of breath	71	88	17	75
Loss of weight	3	4	2	8
Night sweats	2	2.5	—	—
Swelling of legs	20	25	3	12.5
Pain—Slight	30	37	10	41
" Moderate	13	16	5	20
" Angina pectoris	9	11	1	4
Cough	13	16	—	—
Haemoptysis (no aneurysm)	7	9	2	8
" (with aneurysm)	3	4	—	—
Epistaxis	2	2.5	—	—
Cyanosis	16	20	8	33
Pallor	32	40	2	8
Character of impulse:				
Faint	8	10	3	12
Slapping	12	15	3	12
Heaving	33	41	3	12
Signs of cardiac failure	20	25	3	12
Extra-systoles	6	7.5	4	16
Superficial arteries thickened	70	87	17	80

The average age of patients in Group I was 47 years; of those in Group II 49 years. The average time of infection before admission was: in Group I 25 years (24 cases); in Group II 24 years (7 cases).

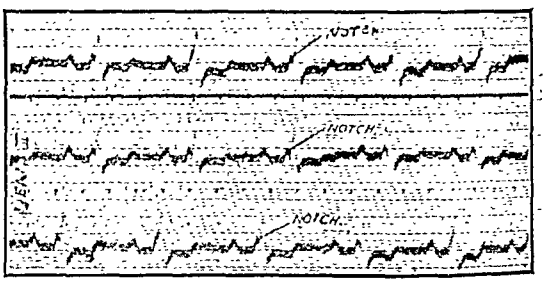
Enlargement of the heart was detected in the groups of cases to the following extent. In the first group (of 81 patients with valvular involvement) slight enlargement of 3¾ inches or less from the mid-line to the left occurred in 2 cases (3 per cent. of the group); of moderate degree, 4 to 4¼ inches from the mid-line, in 13 cases (16 per cent.); and of great degree, or more than 4¼ inches, in 62 cases (77 per cent.). In the second group (of 24 patients without valvular involvement) the corresponding figures were: slight enlargement, 6 cases (25 per cent.); moderate, 4 cases (17 per cent.); great, 10 cases (42½ per cent.). Enlargement of the heart half an inch to the right of the right margin of the sternum was found in the first group in 21 cases (26 per cent.); an increase of 1 inch in 18 cases (23 per cent.); and an increase of 1½ inches in 7 cases (9 per cent.). In Group II the figures were: half an inch in 6 cases (25 per cent.); 1 inch in 2 cases (8 per cent.); 1½ inches in 1 case (4 per cent.). The average systolic pressure in the two groups was 154 in Group I and 141 in Group II. The pulse pressure was 86 in the first group and 52 in the second, while the difference between the systolic pressures of the leg and arm was 51 in the first group and 28 in the second.

The symptomatology of the two groups is not very dissimilar. There were no complaints of cough or bleeding from the nose in the patients who had no organic valvular lesions. Shortness of breath, the earliest symptom of failure of compensation, was somewhat more prevalent among the valvular group. Unusual symptoms were night sweats, haemoptysis (without aneurysm), and loss of weight. There was no evidence of pulmonary tuberculosis or of secondary infection of the cardiac valves in these cases.

Clinical Signs.

Thickened superficial arteries were not invariably present. The average systolic blood pressure in the brachial arteries was about 150 mm. of mercury; extremes (110 to 200) occurred, but were exceptional. At this particular time of life (45 to 50) arterio-sclerosis of a different type exists—the arterio-capillary fibrosis of Gull and Sutton. This is accompanied by a blood pressure higher than 150 systolic as a rule.[1] Where a systolic blood pressure of above 150 was found in the syphilitic cases there were probably other factors—either a high degree of aortic incompetence, or a complication of this diffuse form of

arterio-sclerosis. The blood pressure in the leg was generally higher than that in the arm, especially in the cases of aortic regurgitation. Dr. Strickland Goodall has pointed out that for a given degree of aortic regurgitation the greater the difference between leg and arm systolic pressures the better the prognosis. Dr. Goodall explains the difference as due to the existence of good vasomotor control. In a failing case of aortic regurgitation this control goes and the difference of pressure becomes less; hence the importance of this factor in immediate prognosis.



Enlargement of the Heart.—In the majority of cases the heart was greatly enlarged, but this was not restricted to cases of aortic regurgitation. The amount of enlargement varied with several factors—namely, the amount of regurgitation, the systolic blood pressure, and the state of compensation. In certain of the non-valvular cases with good compensation there was an enlargement of five inches to the left of the mid-line with a systolic blood pressure of 140 mm.; hence there was some other factor present which was not determined.

Aneurysm.—Of the 19 cases of aneurysm in this series aortic regurgitation was present in 17. In 15 of these the average systolic blood pressure (brachial) was 154 mm.; one patient had a pressure of 204 mm., but this must be regarded as exceptional. The height of blood pressure has no bearing on prognosis in these cases. It would be expected that those with the higher blood pressure would rupture the sac and die the earlier, but two patients with systolic blood pressures of 110 and 120 mm. respectively died within two years. Of the 19 patients, 10 had died within two years of diagnosis, and 5 were known to be alive; one patient was alive seven years after the diagnosis. The aneurysmal sac was seen and confirmed by x-ray screening in each case. The sac was situated intrapericardially in one case; it involved the ascending aorta in 7 cases; the arch in 6 cases; the ascending aorta and arch in 2 cases; the arch and thoracic aorta in 2 cases; and the thoracic and abdominal aorta in one case. There was also one case of aneurysm of the right coronary artery. The pressure of the aortic aneurysm was not accompanied by enlargement of the heart in one case of this series; there was no valvular lesion, and the systolic blood pressure was 130 mm. of mercury. Another patient died from a huge aneurysm involving the descending thoracic and abdominal aorta. He was a large man and a stoker by trade; his heart weighed 14 oz. *post mortem.*

Various Minor Signs.—Of the 105 cases albumin was found in the urine of 18 cases only; it was not a constant constituent. Albuminuria is therefore not a sign of cardio-vascular syphilis; its occasional appearance is not explained, as it was present in cases without cardiac failure and without renal involvement. In syphilitic heart disease tachycardia of high degree plays no part. The highest pulse rate of each patient while in hospital was recorded; the average of these rates was 105 a minute. The cardiac pain might be described as mild, moderate, and severe. The mild type was limited to the precordium, the moderate type radiated somewhat, and the severe form had the distribution of classical angina pectoris. These three types were phases of the same symptom, for in several cases the mild type became more severe with progress of time. About 75 per cent. of the patients had cardiac pain in the course of the disease—an incidence greater than that of other forms of heart disease. There were 10 cases of auricular fibrillation and 21 cases of heart-block; in 14 of the latter the auriculo-ventricular interval was greater than one-fifth of a second, 4 had a right bundle lesion, and one a complete auriculo-ventricular dissociation. One had an acute gummatous infiltration of the main bundle with invasion of other parts of the heart musculature. The latter case cleared up completely with treatment. Three of the patients with heart-block had Stokes-Adams attacks with loss of consciousness and twitchings; in these three the attacks were of short duration only. Involvement of the central nervous system was indicated as follows. In one case there was a pseudo-bulbar paresis. The tendo Achillis reaction was absent on one or both sides in 9 cases, and the knee-jerks in 4. In 4 cases the pupils were of the Argyll Robertson type; in 3 cases they were unequal; in 2 irregular; and in 2 sluggish in reaction to light.

Electro-cardiographic Findings.

Electro-cardiographic investigations were made in 66 cases with aortic incompetence, and in 19 cases without organic valvular lesions. Of the latter, 6 showed left ventricular preponderance; some of these had a normal systolic blood pressure; 44 of the 85 cases photographed showed this type of preponderance. Fifteen cases showed inversion of the T wave in the second lead. In cases where electro-cardiographs were taken at intervals of months there occurred an improvement in the general condition, where there was a change from an inverted T to an upright T. Forty-nine of the other cases showed delay, or delay and diminished amplitude of the wave. Of 85 patients 64 showed changes in this wave. Among those dead at the end of 1923, 21 cases had been electro-cardiographed; 15 showed changes in the T wave; of the other 6, 2 had aneurysms, one had a bizarre Q.R.S. complex in one lead, one had heart-block, and the last had auricular fibrillation. There is evidence here that changes in the T wave in the second lead are significant of severe myocardial damage.[2] Another point of importance in these photographs is the appearance of a small notch in the Q.R.S. complex (see accompanying tracing).

If this notch is seen in a case of unknown etiology a Wassermann test should be performed. The pathogenesis of this notch is unknown at present; it appears occasionally in other cases of myocardial mischief than those due to syphilis, and it renders the prognosis somewhat more serious. Twenty-five patients of the series showed this notching; of these, 6 were dead in 1923, one was alive three years and one four years after it was found. In the others this notch was noticed only in 1923 and the majority seemed to have a serious prognosis according to clinical findings. Two patients in whom the notching appeared in a series of photographs died during their stay in hospital. In a third patient the notching became less under treatment and he improved in health at the same time. In one case the T wave in the second lead became depressed during the attacks of angina pectoris. Willius and Barnes from the Mayo Clinic report similar occurrences with myocardial infarction.[3]

Mortality.

Down to the end of 1923 thirty patients had died out of 105, or 28 per cent.; 21 cases were not traced, hence the mortality was 36 per cent. of the total number traced. The average duration of symptoms before death was 4.2 years, the limits being one to twenty-two years. The deaths occurred on an average one year after the first admission to hospital. The course of the disease is rapid when once established. In 28 of these cases the heart was greatly enlarged; of the 2 other patients one had heart-block with Stokes-Adams attacks and the other had angina pectoris. A grave prognostic value must be attached to the signs of cardiac failure—namely, venous pulsation signs at the bases of the lungs, oedema of the legs, enlarged liver of the congestive type, and ascites. One or more of these signs had appeared in 22 of the 30 cases; 14 other patients showed some signs of cardiac failure and were not dead by the end of 1923.

Ten cases of auricular fibrillation occurred in the series; of these, 2 patients died. Some were known to have been fibrillating for several years. There were 21 cases of heart-block and 5 patients died. Six patients had bundle lesions or auriculo-ventricular dissociation; of these, 3 died and 3 were seriously ill.

Nine patients who died had aneurysm of the aorta; one

had aneurysm of the coronary artery. Angina pectoris occurred in 10 cases and 3 patients died. Among 11 necropsies no gross changes were found in the kidneys. In 2 cases adherent pericardium was found. The weight of the heart ranged from 23 to 32 oz., all being much enlarged. It appears that syphilitic pericarditis is a clinical entity; it was diagnosed in yet another patient who did not die. In South Africa a haemorrhagic blood-stained pericardial effusion occurs in natives with a positive Wassermann reaction in the serum; this is relieved by tapping and antisyphilitic measures.

Distinction between the Aortic Regurgitation of Rheumatism and that of Syphilis.

Rheumatic cases generally appear in young adults; syphilitic cases in the middle-aged. A history of the rheumatic infection may often be found, whereas that of syphilis is most difficult to elicit; it was only present in 27 per cent. of this series.

In the great majority of rheumatic cases there is a definite stenosis, with the typical facies; the aortic valve is generally the first to be involved in acute rheumatism. Confusion is caused sometimes by the occurrence of the presystolic murmur at the apex in cases of pure aortic regurgitation (Austin-Flint murmur). The distinction may be made by (1) the facies; (2) the pulse pressure, which is greater in aortic regurgitation with the Austin-Flint murmur, smaller in mitral stenosis and aortic regurgitation; (3) the pulmonary second sound is accentuated in mitral stenosis.

As pointed out by Dr. Strickland Goodall, in rheumatic cases the general progress of the disease is from the left cusp of the mitral to the left posterior cusp of the aortic valve; they have a common blood supply, and the aortic wall is not affected as a rule. The diastolic murmur is therefore blowing in character, and its area of maximum conduction is down the left side of the sternum. In syphilis the aorta is roughened, and the cusp most often involved is the right posterior. Hence the murmur is harsh in quality and the maximum conduction is down the right side of the sternum. In syphilis the accompanying signs in the central nervous system are of great diagnostic value. The arteries are thickened in pure rheumatic cases only where the pulse pressure is extremely high from large degree of aortic regurgitation.

Treatment.

Large doses of potassium iodide were usually employed, and mercury by inunction of blue ointment; in some cases arsenobenzol compounds were given intramuscularly. The intravenous administration was followed by some fall of blood pressure. The impression received from the cases directly supervised was that arsenobenzol compounds were unsuitable for the later stages of cardio-vascular syphilis. Digitalis was used in conjunction with iodides and mercury where cardiac failure was present.

In two cases of aneurysm of the aorta pain was greatly relieved by the administration of doses of horse serum twice a week or of haemoplastin twice a week. The explanation offered is that clotting was produced in the sac.

Conclusion and Summary.

1. The age incidence, the sex incidence, and the latent period after infection are similar in cardio-vascular syphilis and tabes dorsalis.

2. Once the symptoms and signs of cardio-vascular syphilis occur the course of the disease is, as a rule, rapid.

3. Signs in the nervous system are important in making a diagnosis.

4. The initial symptom is not constant, but in the majority of cases is either shortness of breath or cardiac pain, and, less often, giddiness and palpitation.

5. Cyanosis occurs in a greater percentage of cases without aortic regurgitation, and pallor in a great percentage of cases with aortic regurgitation.

6. The superficial arteries are thickened in the majority of cases, but the blood pressure is rarely above 150 mm. of mercury. Such a thickening with a similar rise of blood pressure occurs in the senile form of cardio-vascular degeneration.[1] Systolic blood pressure in the leg is greater than that in the arm, especially in cases with aortic regurgitation.

7. The heart is often much enlarged even in cases with no aortic regurgitation, and where the blood pressure is low.

8. A syphilitic myocardial degeneration may occur without valvular mischief, and sometimes without thickening of superficial arteries.

9. Cardiac pain is often mild in degree at the beginning and progresses to true angina pectoris.

10. Different portions of the heart and blood vessels are affected maximally in different cases.

11. There is often an inconstant albuminuria of no significance.

12. The electro-cardiograph findings which have a prognostic value are: (*a*) Changes in T wave in lead 2. (*b*) Occurrence of interference in auriculo-ventricular conduction. (*c*) Notching of the Q.R.S. complex. (*d*) Auricular fibrillation.

13. The signs of cardiac failure are also of prognostic significance.

14. The *mortality of the disease is high*, once it has passed out of the latent stage.

15. It is necessary to diagnose these cases in the latent stages so that treatment may be more successful.

16. The distinction between aortic regurgitation of syphilitic and of rheumatic origin is necessary on clinical grounds.

17. Haemostatic serum is useful in certain cases of aneurysm with pain.

My thanks are due to the honorary staff of the National Hospital for Diseases of the Heart, London, for permission to use their records, and particularly to Dr. Strickland Goodall for his kind advice and elucidation of several matters in the text.

THE EFFECT OF POSTURE ON CASES OF PNEUMOTHORAX.

BY

L. S. T. BURRELL, M.D.CANTAB., F.R.C.P.LOND.,

PHYSICIAN TO THE BROMPTON HOSPITAL; ASSISTANT PHYSICIAN TO THE WEST LONDON HOSPITAL.

WHEN a patient with pneumothorax moves from side to side or from the recumbent to the erect position the intrathoracic pressure is altered, and the intrathoracic viscera and any effusion that may be in the pneumothorax cavity are also moved.

Intrathoracic Pressure.

Dr. Lawson[1] pointed out that this pressure varies with posture in cases of artificial pneumothorax. The variation may be very considerable, and this should always be borne in mind when giving a refill. Some physicians give refills with the patient sitting in a chair, others with him lying flat on his back, and others with him lying completely or partially on one side. If we have records of previous refills it is usually possible to tell in what position they were given by putting a needle into the pneumothorax cavity and moving the patient until the usual pressure is found. If the patient lies on the pneumothorax side the weight of the viscera will render the intrathoracic pressure in the pneumothorax cavity higher than if he lies on the healthy side. In one of my cases the pressure was −4+2 with the patient lying on the left (pneumothorax) side, but −10−0 when he was lying on the right side. After a refill of 450 c.cm. of air the pressures were +1+3 and −5+2 respectively. In other words, when this patient was lying on the healthy side he could raise the pressure in his pneumothorax cavity as much by turning on to the treated side as by having a refill of 450 c.cm. It is possible, therefore, to use posture if we wish to stretch adhesions, for by making the patient lie on the healthy side a continual drag on the adherent areas would be produced. Of course posture will affect the

intrathoracic pressure more when the lung is free than in cases where it is bound to the chest wall by adhesions or adherent pleura. It will also have a greater effect if the mediastinum is freely movable.

Position of the Thoracic Viscera.

By making an *x*-ray examination of the patient in various positions it is possible to judge to what extent the mediastinum is movable and also to see exactly where the lung is held up by adhesions and where the visceral pleura is in contact with the chest wall but not actually

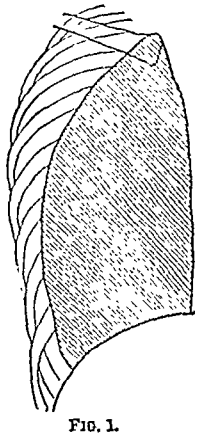

FIG. 1.

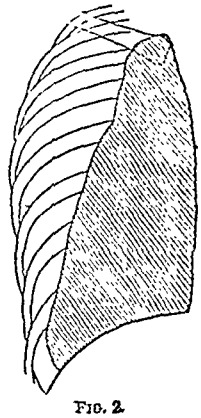

FIG. 2.

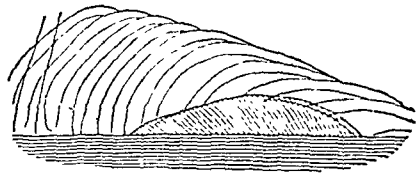

FIG. 3.

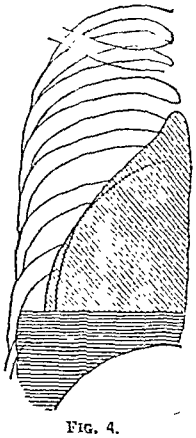

FIG. 4.

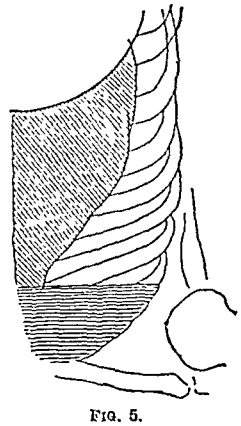

FIG. 5.

adherent. Fig. 1 shows a case of artificial pneumothorax with the patient in the recumbent position. Fig. 2 shows the same patient in the erect position, and it will be seen how great is the difference in the position and shape of the lung.

Effusion in the Pneumothorax Cavity.

Of course fluid is freely movable in these cases, and it can readily be shifted by making the patient lie on one side (Fig. 3), if it prevents a good *x*-ray examination of the diaphragm or base of the lung, as in Fig. 4; or if he is active and sufficiently well he may stand on his head, when the fluid will *gravitate to the apex* and a clear view of the base will be obtained by *x* rays (Fig. 5).

My thanks are due to Dr. Stanley Melville, who took the skiagrams from which these tracings are made.

A CASE OF TUMOUR OF THE BRAIN WITHOUT SYMPTOMS.

BY

SYDNEY SMITH, M.D., D.P.H.,

PRINCIPAL MEDICO-LEGAL EXPERT, EGYPTIAN GOVERNMENT SERVICE.

THE case here recorded has a certain clinical interest and is of some importance from the medico-legal point of view.

An elderly male Egyptian was knocked down by a motor car whilst crossing the street, and was removed to hospital in a semi-conscious state.

On admission the pulse was 100, the pupils equal and reactive to light, there was no Babinski sign, and the deep reflexes of the legs were exaggerated. There was paresis of the left arm and spasticity of the other three limbs. The cerebro-spinal fluid was found to be of normal tension and was discoloured with blood.

The patient gradually got worse, and died five days after admission without regaining consciousness. His temperature gradually rose to 38.4° C. before death, and his respirations rose from 24 to 38 per minute.

On dissection a bruise was found in the temporal muscle above the right ear, and under this a linear fissure in the skull running forwards and downwards into the middle fossa and terminating in the right sphenoid bone. There was about 1 c.cm. of clotted blood between the dura mater and the bone in the region of the crack. The dura was thickened and adherent. The brain was intensely congested and the pia arachnoid looked blood-stained, although no actual extravasated blood could be observed. The brain was not damaged on the side of the injury, but on the opposite side there were two lacerations—one the size of a shilling on the left temporal lobe where it rested on the petrous temporal bone, the other about half the size towards the temporal pole adjacent to the small wing of the sphenoid. There were no other signs of violence, nor haemorrhage into the brain substance. On section, however, two tumours were found in the right hemisphere—one situated in the anterior part of the Sylvian fissure where the horizontal and ascending rami take origin, the other situated at the end of the sulcus temporalis superior in the gyrus angularis. Neither of these tumours could be seen on the surface, but on making serial horizontal sections the following relations could be ascertained.

A. The anterior tumour had no distinct boundaries, it took origin between the pia mater and the arachnoid, invaded the brain substance forwards into the frontal lobe and upwards into the pars triangularis, and reached the white matter of the middle temporal gyrus. The anterior extremity reached the roof of the anterior horn of the lateral ventricle. The grey and white matter of the island of Reil, the claustrum, and the external capsule were destroyed in their anterior half. The tumour touched the anterior extremity of the lenticular nucleus and destroyed the lateral part of the internal capsule at the level of the head of the caudate nucleus. Above the level of the basal ganglia there were several small cavities, one of which was 5 mm. in diameter.

B. The posterior tumour consisted of a well defined cheesy mass measuring 1.5 by 2 cm. and was enclosed in a capsule. It destroyed the grey matter of the angular gyrus and invaded the white matter as far as the forceps major.

On microscopical examination both tumours were found to be of syphilitic origin, invading the brain substance from the pia arachnoid. In and about the tumours the blood vessels showed intense infiltration with lymphocytes, and the brain tissue adjacent to the vessels was in a state of softening. The cavities mentioned above showed degeneration of the brain substance with a neuroglial wall and with a similar condition of the vessels around them.

From the clinical aspect the presence of such extensive invasion of the brain by tumours without apparent symptoms is rather a remarkable feature, and an effort was made to obtain the previous history of the victim. He was, unfortunately, an old man who lived by himself, and we could obtain no information about him except that he had been in a "debilitated" state for about three months, but used to look after himself without assistance and was able to lead an apparently normal life. We could not ascertain from his relatives or neighbours whether he had complained of any symptoms, and presumably he had not.

From the medico-legal aspect the case is important in that it shows that a person may be walking about leading an apparently normal life while suffering from an advanced disease of the brain. When an individual so suffering is the victim of an accident such as this person sustained the question of responsibility must arise, and it is at least an open question whether the central lesion did or did not play a part—first, in causing the accident, and secondly, in leading to a fatal issue after the accident.

We can readily understand that lesions of this extent might at any moment cause an oedema of the brain which might lead either to loss of consciousness or to loss of co-

ordination, and either cause the victim to fall under the car or prevent him from getting out of its way. After such an accident it might easily be believed that an injury to a brain already the seat of advanced disease was more likely to be fatal than would a similar injury in an ordinary brain.

A final point of some interest is the relative position of the site of injury and the position of the so-called contrecoup lesions. The blow struck the head just above the right ear, whereas the two contrecoup lacerations were found on the left temporal pole and on the lower surface of the temporal lobe. These are by no means exactly opposite the site of injury, and are the usual site for contrecoup injuries whatever the site of the original violence.

My thanks are due to Professor O'Farrel and Dr. Boulgakov for their help in the preparation of the case.

ZINC GLYCO-GELATIN:

*SOME OF ITS USES IN GENERAL PRACTICE.**

BY

W. MUIR SMITH, M.B., C.M.GLASG.,

EASTBOURNE.

THE merits of zinc glyco-gelatin were first brought to the notice of the profession by Unna for its efficacy in the treatment of dry forms of eczema, but, as far as I am aware, this plastic amalgam has not yet received a place in the equipment of the general practitioner, and it is the contemplation of this anomaly in the usual custom and fashion of the profession that induces me to bring to your notice the result of my experience of its use, now extending over twenty years, in other conditions which are met with in everyday practice—such as arthritis, dermatitis, erysipelas, erythema nodosum and simplex, myositis, periostitis, phlebitis, and varix of the leg, synovitis, "tennis leg," minor thrombosis, contusions, and sprains of the joints of the limbs, to mention the chief.

The amalgam employed in these cases is composed of oxide of zinc 1 part, gelatin 2 parts, glycerin 3 parts, and water 4 parts, prepared and compounded by a skilled pharmacist. When once the principle of the rationale has been grasped the selection of cases becomes comparatively easy, but it should also be realized that, as so much of the after-success depends upon the care devoted to technique, the task should not be undertaken in a perfunctory fashion. By way of illustrating what these injunctions imply, take the condition of a leg (by far the more common part) requiring a dressing. The following outline of directions, which, in principle, apply to all cases, naturally falls under two headings—preparation and application.

Preparation.

1. If necessary, previously instruct the patient to remain in bed for such a time as is likely to allow oedema to subside to a minimum.
2. Set the process of melting the solid amalgam going.
3. Thoroughly sponge the surface extent with methylated or rectified spirit twice or thrice over, to remove fatty excretions and loose epithelium.
4. Dredge the surface well with a dusting powder composed of calomel one part and starch four parts, using the palm of the disengaged hand to rub it uniformly all over.
5. Select an open-wove bandage (texture used throughout) of an appropriate width, and cut it into a sufficient number of strands to encircle the leg from the ankle to the knee-joint, due provision being made (in the form of a "many tail" arrangement) for allowing each strand to overlap the other, by half of its width, and, at its junction in front, the ends to overlap one another by two inches, in the series of their implacement from below upwards.

Application.

As the paste, when spread, cools and sets quickly, it is advisable to apply the *immediate* part of the dressing in two sections—namely, lower, from the upper border of the ankle-joint to the commencement of the calf; and upper, from the junction of the calf to within half an inch of the knee-joint.

1. With a brush, as rapidly as possible, apply a coating of the paste over the lower section, but leaving the flexure of the ankle-joint free, by demarcating the lower boundary of the painted extent along the upper border of the joint, from a middle point in front, outwards and downwards, on each side, including both malleoli, to short of the plantar border of the heel, then continued posteriorly to meet at a point just above the insertion of the tendo Achillis.
2. Apply the strands in their "many tail" order over the painted extent, due tension the while being maintained by the hands between the ends so as to secure uniform and even apposition of the fabric to the surface.
3. Over the implaced strands run a single length of a continuous bandage, avoiding "reverses" here (which at no stage should ever be plied over the crest of the tibia); if uniformity cannot otherwise be secured, then cut the length, fix the free end down with a daub of the paste, and encircle anew, and thereafter firmly pass the hands, one on each side, over the bandaging, in a series of semicircular sweeps from below upwards.
4. Repeat 1, 2, and 3, on the upper section, which completes the application of the *immediate* part of the dressing.
5. Rapidly apply a second coating of the paste over the *whole* bandaged extent.
6. Over this run a second bandage, but applied in the opposite direction to the first, the hands being used as before; thereafter ("reverses" on either side being now permissible) run a third and a fourth bandage in alternate directions, the hands being used in the same way, which completes the affixation of the zinc glyco-gelatin dressing.
7. Finally, encompass the foot, from behind the toes, and the ankle with a bandage, in the usual fashion, which finishes the complement of the whole appliance.

While the surface should be unbreached and free from exudations, yet dry incrustations firmly adhering to the skin, which maceration with spirit has failed to detach, should offer no barrier to the choice of selection of cases. Except for the purpose of treatment, flexures of joints, which come into play, should not be included in the immediate dressing. In the case of the ankle-joint the same purpose is equally well served by the method of No. 7, which possesses the inestimable advantage over the orthodox instructions of permitting the bandage to be renewed as often as hygienic attention to the foot may demand, without impairing efficiency.

As a rule, first and second dressings should last from three to six months, and, on an average, third and subsequent dressings should remain serviceable from nine to ten months, or even longer. Fortified with this appliance, in about 95 per cent. of leg cases patients are enabled to walk about, while treatment is going on, in conditions of (*a*) subacute and chronic varix, immediately; (*b*) dermatitis, erysipelas, erythema nodosum, and periostitis, within a week; and (*c*) arthritis, myositis, phlebitis, synovitis, and minor thrombosis, within a fortnight—respectively after the affixation of the dressings. On a minimum enumeration of the records traceable, over seventy cases belonging to the varix category, and more than forty cases of the other classifications, have been treated during the past twenty years with unqualified benefit to the patients; and I venture to claim for this method of treatment, on the average of selected cases (in addition to its outstanding merit of enabling the patient to walk about, as aforementioned), a greater measure of all-round efficiency, in the way of (1) affording the comfort of relief from pain, (2) preventing the development of complications in the affected areas, and (3) effecting a cure, or expediting the recovery, or promoting the betterment, of the morbid conditions, than could have been hitherto, or can be at present, obtained from any of the other forms of treatment known to me in the course of over forty years' experience of general practice.

A précis of one classic case may suffice to convey some idea of the changes which this appliance is capable of effecting in a morbid condition which the practitioner has hitherto regarded with a *non possumus* attitude to benefit from any form of treatment whatsoever.

Mrs. M., aged 50 years, figure short, rotund, and expansive, weight 17 st., had for twelve years been afflicted with a varicose ulcer on each leg, deeply eroded, and of diameter 3½ and 3 in. respectively. After months of ordinary treatment the ulcers healed. The case was selected—with misgivings—for zinc gelatin treatment.

Before treatment the girth of the legs, at the middle of extent of lower section, measured 12 and 11½ in. respectively; the structures were thickened and indurated, deeply brawny and tender, and the outline of the venous main and anastomotic

* Abstract of a paper read before the Eastbourne Medical Society.

branches everywhere undefinable on the inner surface of the lower section.

After treatment the girth of legs, at same mesial, measured 9¼ and 9 in. respectively; the structures were soft and pliant, colour more normal and no longer tender, and outline of the same venous system easily delineated, and, with the exception of a few scattered indurated valvular pouches, the lumen of the vessels appeared to be more or less patent throughout the lower section of both legs; while over the sites of former ulceration extensions of vascular branches are plainly discernible injecting the waxy white cicatricial coverings with fine arterioles and network of venules from around their marginal borders.

These, then, comprise the salient features of the comparative changes which had been effected, in this instance, by means of a renewal of the dressings, on an average of once in ten months, for close on seven years, when the dressings were tentatively discarded in favour of ordinary roller bandaging support, which the patient continuously wore, in her household work, during the remaining thirteen years of her life, without any threat of recurrent ulceration or sign of varicosé stagnation in the interval.

I think we have ample evidence here suggestive of the appliance being no ordinary implement of a mechanical contrivance, and that the amalgam is potential of some therapeutical virtue the unusual results in this instance would seem to imply. And what has been accomplished in this instance is but a replica, of outstanding dimensions, of the imprimatur of restorative benefactions conferred upon the recipients in each of the other sixty-nine cases of more or less chronic varix. And what is true of chronic cases equally applies to those of the acute and subacute classifications; and I know of no other form of treatment which gives such speedy relief to the agony of the victim of "tennis leg" as the envelopment of the limb in a glyco-gelatin dressing.

Whatever may be the explanation of its rationale of action, if it were only for its *par excellence* efficiency in chronic varix and acute phlebitis of the leg (whereas in the former it stands alone, and in the latter it has no compeer, as far as known, in present-day therapy) the zinc glyco-gelatin appliance should merit an abiding place in the armamentarium of every well equipped general practitioner.

A NOTE ON TWO CASES OF A FOREIGN BODY IN THE URINARY BLADDER.

BY

HUGH LETT, C.B.E., F.R.C.S.,

SURGEON TO THE LONDON HOSPITAL.

THE two cases here recorded are of interest as they illustrate some of the complications which may result from the presence of a foreign body in the bladder.

CASE I.—*Perforation of Bladder Wall: Haematuria: Perivesical Abscess.*

The patient, a girl aged 19, was admitted to the London Hospital under Dr. Cecil Wall, who kindly referred her to me. She stated that she was quite well and free from symptoms until five days previously, when she noticed that the urine was deeply stained with blood. The haematuria persisted until her admission to hospital. She also complained of pain and tenderness in the left iliac fossa, and slight pain on micturition in the hypogastrium and urethra. She said that the frequency of micturition was not increased.

For the first two nights after admission her temperature was raised to 99.2° and 100°, but subsequently became normal.

On abdominal examination a hard, tender fixed lump was felt in the left iliac fossa immediately above the inner half of Poupart's ligament. A skiagram showed a rod-shaped body lying transversely in the bladder, and projecting beyond the brim of the true pelvis on the left side. Cystoscopy confirmed the skiagram, and the foreign body was recognized as a penholder, painted with blue and red stripes, and encrusted with phosphates. There was oedematous cystitis on either side where it was in contact with the bladder wall. The urine was deeply stained with blood.

Suprapubic cystotomy was performed and the penholder removed. It was 13 cm. long, made of wood, and was firmly fixed. On the left side it had perforated the bladder wall, and its point extended into the indurated swelling above Poupart's ligament. The swelling was incised, and a small amount of pus escaped. The bladder and abscess were drained. The wound healed rapidly, and the patient passed all her urine naturally on the tenth day after operation.

CASE II.—*Large Vesical Calculus: Incontinence.*

The patient, a single woman, aged 59, was brought to the cystoscopy department of the London Hospital on June 27th, 1924, complaining of incontinence of urine. She had been perfectly well until June, 1923, when she found that she could not control her bladder, and had great frequency of micturition. She wetted her bed at night and her clothes [illegible] became worse, until the urine dripped aw[illegible] as given a portable urinal, but it was not [illegible] seldom went outside the house. During t[illegible] had lost a great deal of weight and strength, and had suffered considerably from thirst and a dry mouth. The bowels were constipated, with occasional attacks of diarrhoea. Her urine had been thick and offensive for some time, but there had been no haematuria.

The patient was a thin, wasted, rather excitable woman. She was somewhat unstable mentally, for she had unaccountable fits of giggling, and was very vague as to the history of her illness. Her friends stated that she had "always been a bit queer." The tongue was dry and furred.

Abdominal examination revealed a round, hard mass immediately above the pubes. This mass was also felt through the anterior wall of the rectum. Examination of the external genitals showed great hypertrophy of the labia minora. The urine was alkaline and extremely offensive; it contained a thick white deposit of pus and phosphates, and one-third volume of albumin. Clinical examination was otherwise negative. The systolic blood pressure was 104 mm. of mercury, the diastolic 70 mm.

Skiagrams of the pelvis showed a large calculus in the region of the bladder, with a long narrow shadow of greater density running through it transversely.

Operation.

On July 1st, 1924, suprapubic cystotomy was performed. The bladder was adherent to the wall of the pelvis on either side and anteriorly to the back of the pubes, while superiorly the peritoneum was stripped off with great difficulty. The bladder was entirely occupied by a phosphatic calculus surrounding the foreign body. The stone crumbled under the fingers, and was removed piecemeal. The foreign body was wedged firmly across the bladder, and could not be removed until the bladder incision had been extended laterally to the right.

On examination of the empty bladder a pouch was found on either lateral wall, corresponding to the extremities of the foreign body. Two drainage tubes were placed in the bladder, one for irrigation and the other for drainage, and the bladder wall was closed round them with catgut. A glove drain was placed in the cave of Retzius.

The accompanying figure shows the foreign body and the fragments of the stone. The foreign body proved to be an ivory penholder, 9.6 cm. long and 0.55 cm. in diameter. The fragments of stone weighed 44.1 grams and the foreign body 6 grams, so that the total weight was rather more than 1½ ounces. The stone was composed of calcium phosphate with a trace of oxalate.

Convalescence was slow but uneventful, and the patient was finally discharged from hospital on August 12th, six weeks after the operation, with the wound healed.

On September 26th she came back with a history of occasional leakage through the suprapubic wound. The wound, however, appeared to be soundly healed, and she was discharged after six days.

On October 24th she was seen again in the cystoscopy department, feeling and looking very well. She could walk about well, and had perfect control over her bladder. She was able to go all night without passing urine, and the average interval between the acts of micturition during the day was four hours. The bladder capacity was 6 ounces.

The usual complication of a foreign body in the bladder is, of course, a deposition of phosphates which gradually forms a calculus with the foreign body as its nucleus; but in the first case the foreign body gave rise to a comparatively rare complication—namely, the perforation of the bladder wall with fairly profuse haematuria and the formation of a perivesical abscess.

In the second case the most striking symptom was the incontinence, for which the patient had to wear a urinal. Further points of interest, apart from the size of the calculus, were the adhesion of the bladder to the pelvic wall and the impaction of the foreign body in the bladder, so that it could not be removed until a very large opening had been made.

That the wound should have taken six weeks to heal soundly was not unexpected in view of the foul state of the urine, the severity of the inflammation of the mucous membrane, and the size of the bladder incision.

The remarkable power of recovery latent in the bladder wall is illustrated by the fact that the patient could easily retain 6 ounces of fluid and empty the bladder completely some fourteen weeks after the wound had healed, although she had previously been incontinent for a year.

Memoranda:

MEDICAL, SURGICAL, OBSTETRICAL.

CELLULITIS OF THE SCALP TREATED BY INTRAVENOUS COLLOIDAL SILVER.

I THINK that the following case is of interest as it would appear to indicate a simple treatment for a serious condition.

On November 29th, 1926, a woman, aged 62, was admitted to Andover War Memorial Hospital suffering from a scalp wound in the occipital region (about 1½ in. long) and a mild degree of concussion. For the next few days she ran a high evening temperature and looked very ill. She complained only of severe headache and had all the appearances of suffering from a toxaemia against which she was incapable of fighting. A thorough general examination failed to reveal any definite cause for her condition. The only fact noted was that the wound, though not discharging, was gaping and showing no signs of healing.

On December 6th the diagnosis of the patient's condition was made obvious by the appearance of an isolated patch of cellulitis over the forehead. She looked so ill as to appear almost moribund. On the following day the affected area had extended, although the inflammation seemed, if anything, less intense.

An intravenous injection of 10 c.cm. of collosol argentum was given. There was a striking and immediate improvement in the patient's condition, and two days later the cellulitis had almost disappeared, the tongue was clean, and there was no headache. The edges of the wound, which was now discharging slightly, looked healthy, and had approximated. The treatment was repeated, and the patient made an uneventful recovery, being discharged well on December 21st.

So far as I am aware, colloidal silver has not been previously used in a similar case.

Andover, Hants. R. S. WEIR, M.B., Ch.B.

POTASSIUM SILVER IODIDE IN THE TREATMENT OF GONORRHOEA.

THE double iodide of potassium and silver ($KAgI_2$) is a crystalline substance readily soluble in a small quantity of water. On dilution the solution begins to precipitate silver iodide, but the precipitation is not complete until a fairly high dilution is reached.[1] The precipitated silver iodide is in a very finely divided condition and a part of it is in a colloid state. It has a tendency to creep up and adhere tenaciously to the sides of a test tube, and would presumably creep into the crypts and ducts of the urethra and adhere to them and to the gonococci found there. The unprecipitated portion is still in the form of a double salt and in a state of molecular dispersion. In this condition it would presumably diffuse through the walls of the cells, and on being further diluted by the tissue fluids would precipitate more silver iodide inside the tissues. The decomposition of the double salt on dilution tends to be reversed by the presence of excess of potassium iodide.

The potassium silver iodide was prepared as described by Mellor (*loc. cit.*). One part by weight of crystallized potassium silver iodide and four parts of potassium iodide were intimately mixed and dissolved in water as required in the strengths of 0.5 gram, 1.0 gram, and 1.5 grams, in 20 c.cm. in each case. Each of these dilutions contains a fine suspension of silver iodide, some of it in a colloidal state, and a true solution of the double salt.

Method of Treatment.

Of the above solution 20 c.cm. is placed in a glass syringe. The tip of the syringe is introduced into the meatus and the solution is injected slowly and steadily, with the fingers grasping the glans to prevent escape of the fluid. At the same time the patient is asked to keep his nostrils closed and breathe freely through the mouth. After injection a soft bandage is applied over the glans tight enough to prevent the injected fluid from coming out. The bandage can be removed after fifteen to thirty minutes. The injection distends the urethra fully, opening out the crypts and recesses, and a portion perhaps enters the bladder. The solution seems to reach the prostate and seminal vesicles, as on massaging the prostate and vesicles two or three days after the injection the expressed fluid is seen to contain some silver iodide. In acute cases the anterior urethra is washed out twice, using 10 c.cm. of the first strength each time, before the injection of 20 c.cm. is given, and the bandage applied. In chronic posterior urethritis an injection of the second strength is given after urination, with prostatic massage, and later in the treatment the third strength is used. The treatment has the advantage that the injections need only be given twice or thrice a week, as the silver iodide persists in the urethra and continues to exercise its antiseptic action.

Results.

Under this treatment the discharge decreases very rapidly and after about six injections disappears, though in many cases on prostatic massage a few extra-cellular diplococci may be detected microscopically in a smear. After about twelve to fifteen injections gonococci completely disappear, and even after provocative treatment and prostatic massage a smear shows their absence. Cases which come with a stricture do not readily respond unless the stricture is dilated prior to the injection. Cases of prostatitis, vesiculitis, and cystitis respond readily. A case of gonorrhoea with acute retention of urine was treated by hot hip baths with repeated catheterization and injections. The patient recovered rapidly.

I wish to thank Major Clive Newcomb, I.M.S., chemical examiner to the Government of Madras, for his guidance and help, and Lieut.-Colonel R. B. B. Foster, I.M.S., superintendent of the Government Royapuram Medical School, Madras, for permission to publish this note. I am also indebted to my assistants, Mr. N. Raghavayya, assistant lecturer in chemistry, Royapuram Medical School, Madras, and Dr. C. R. Krishna Pillay, for their active co-operation with me.

[Dr. Naidu sends notes of ten cases: in all of them gonococci were detected microscopically in smears, the injections were well borne, and none of the patients complained of any considerable pain.]

GASTRECTOMY FOR SARCOMA OF THE STOMACH.

SARCOMA of the stomach being a fairly rare condition, the following case may be of interest.

A man, aged 27, was admitted under my care to the Victoria Hospital, Keighley, on December 12th, 1926, with a history of indigestion extending over three months. On admission he was much emaciated—the emaciation, he stated, had become very apparent during the previous four weeks. He had severe pain almost immediately after food (even liquids), and there was frequent vomiting. On examination the abdomen was much retracted and a large sausage-shaped tumour could be readily seen and palpated in the epigastrium. The tumour was fairly movable and very tender, even on the slightest pressure.

On December 17th I performed gastrectomy. The tumour was found to involve practically the whole of the stomach, there being only a very small portion of the cardiac end apparently free from disease, which made the anastomosis between the resected end of the stomach and the jejunum rather difficult. The tumour did not involve the duodenum, but there were many enlarged glands in the gastro-colic and gastro-hepatic omenta. One hard nodule was also detected in the liver.

After operation the usual treatment to counteract shock, etc., was carefully carried out, and from the third day after operation

the patient was able to take fluids and meat jellies freely by the mouth, and expressed himself as feeling very comfortable. On the tenth day, however, he died suddenly from heart failure.

The stomach was sent for pathological examination to Mr. Alfred Gough of Leeds, who reported as follows: "The tumour forms a large cake about an inch thick. It lies essentially in the muscular coat. The mucosa extends over it for some distance, gradually thinning out, and giving place to an ulcerated surface covered with granulation tissue. The tumour is composed of spindle cells rather loosely arranged with a good deal of intercellular substance. It is a myxosarcoma."

Boyd, in his book on *Surgical Pathology* (p. 293), under the heading of Rare Conditions of Stomach and Duodenum, says: "Sarcoma of the stomach is of equal frequency in men and women. It is usually of the round-celled variety, but may be spindle-celled. It starts in the submucous coat, and may attain an enormous size, bulging into the cavity or growing outwards to form a mass outside the stomach."

H. STEWART BRANDER, M.D., Ch.B.,
Honorary Surgeon, Victoria Hospital, Keighley.

Reports of Societies.

THE ETIOLOGY OF EPILEPSY.

AT the meeting of the Section of Neurology of the Royal Society of Medicine on January 13th, with Sir J. PURVES-STEWART in the chair, a discussion on epilepsy was opened by Dr. W. ALDREN TURNER.

Dr. Aldren Turner said that the essential feature of epilepsy was a disturbance of consciousness, occasionally sudden, swift, and brief, which might or might not be accompanied by spasm or convulsions. Certain psychical phenomena might be associated, such as dream states and visual hallucinations. There had been a tendency during recent years to broaden the basis of epilepsy mainly from the psychical side, and to regard as epileptic certain states of disturbed consciousness of longer duration, including somnambulism and stupor. It was now generally accepted that there was no single clinical entity to which the name "epilepsy" might be applied. Three special groups were to be distinguished: (1) organic; (2) toxic, infective, or metabolic; (3) psychogenic; other varieties might be designated "epilepsy of unknown origin." The suggestion had been made that the phenomena of epilepsy might be explained by the circulation of toxic substances in the blood, arising, for example, from defective carbohydrate metabolism in the small intestine. There could be little doubt that some cases of epilepsy at the commencement of the illness were attributable to toxic, infective, or metabolic agencies; these included, for example, epilepsy following any of the exanthemata, also a form of epilepsy associated with intestinal stasis and the toxaemia resulting therefrom. A quite unjustified degree of importance had been attached to the relation of epilepsy to glandular disturbance. With regard to the metabolic group of epilepsies, there was considerable clinical evidence in favour of the existence of such a group, but so far convincing biochemical evidence was lacking. Emotional causes had come to be regarded as of great importance, but it was only of recent years that it had been revealed how emotion acted in mental illness. A group of epileptic reactions had been discovered which would appear to be attributable to emotional influences. It was difficult to distinguish between the hysterical and the epileptic type of fit, and certain attacks could not be classified as either. According to some workers, a study of the types of epileptic attack had demonstrated that some disturbance of the emotional state and some reaction against expressing the emotion had been found in every instance, but it was doubtful whether an intensified emotion was sufficient to give rise to that dramatic crisis, the major epileptic fit. The whole subject of the epileptic fit as an expression of an emotional state involving a disturbance of consciousness required fuller examination. It seemed that in all forms of epilepsy an additional factor had to be detected; it would most probably be found in a constitutional defect conveyed through inheritance or acquired later. Dr. Turner had investigated the temperamental qualities of a large number of epileptics; only a few were of the absent-minded and day-dreaming type, while the self-satisfied and self-opinionated also formed only a small group. The outstanding feature of the epileptic temperament was nervousness and anxiety; a great part seemed to be played by fear and apprehension in the development of their mental outlook. There had been a tendency of recent years to under-estimate the importance of inheritance, but in this group of illnesses it was impossible to survey the family history of any large number of epileptics without obtaining direct evidence of epilepsy in the family in quite a substantial proportion of cases. His own investigations, covering quite a large number of cases, showed an hereditary history in 33 per cent.

Dr. GEORGE RIDDOCH said that at the London Hospital during the past two years a number of workers had approached this problem from the clinical and biochemical sides. Most of the questions which they set out to elucidate were still unsolved; notably, the etiology of epilepsy, and the mechanism of the production of the seizure. Very little was known about etiology, and it was difficult to assess the hereditary factor. Family histories were hard to obtain, especially in patients of the hospital class, but at least one-third of the cases of epilepsy studied revealed a definite family history. The old question of insanity and its bearing upon epilepsy had been taken up, and it appeared that mental disorders of that class were *no more* common among epileptics than among non-epileptics. It was found that the epileptics who had a significant family history were the first-born in a disproportionate number of cases, a fact which might point to trauma at birth, resulting in brain lesion. One investigation made at the London Hospital concerned the effect of starvation upon epilepsy. In a number of epileptics it was found unquestionably that starvation lasting for a fortnight, with water only, had a beneficial effect, the fits either ceasing altogether from the beginning of the period or diminishing in frequency; the good effect continued after the starvation period was over. He did not put this forward as a therapeutic method, but only as an investigation. In connexion with the study of the mechanism of the production of seizures, he related some experiments on cats and rabbits in which characteristic convulsions after the injection of certain substances had been investigated. It was also found with these animals that bromide given in increasing doses and increasing concentration gradually diminished the severity of the seizures and finally eliminated them entirely.

Dr. W. RUSSELL BRAIN described the results of biochemical investigations in epilepsy also made at the London Hospital. There was no confirmation of the suggestion that epilepsy was caused by a reduction in the calcium-iron concentration in the body fluids. Hitherto no metabolic abnormality in epilepsy had been conclusively proved or generally accepted, but a good deal of work at the London Hospital had been directed to the study of the blood cholesterol. It had been stated that epileptic women were most likely to have fits at that period in the menstrual cycle when the blood cholesterol was known to be at its minimum, and two French observers had stated that they had found in epilepsy a fall in the level of the blood cholesterol *during the attacks*, though they believed this to be the result and not the cause of the attacks. It was therefore resolved to investigate the behaviour of the blood cholesterol in epilepsy, and the level of the blood cholesterol was thereupon determined in a large number of epileptics. From figures which he exhibited, comprising some thirty or forty normal persons of each sex, and about an equal number of epileptics, it appeared that normal individuals had a higher blood cholesterol content than the epileptics. It was also found that in epileptics from whom blood had been taken within twenty-four hours of the attack the blood cholesterol, both in the whole blood and in the plasma, was considerably lower than in the case of epileptics from whom blood was taken more than twenty-four hours after the attack; in the latter the figures were much nearer to those exhibited by the normals. Dr. Brain concluded that there was a relation between a low level of the blood cholesterol and an epileptic attack. In a few instances which it was possible to observe continuously the attack was found also to be preceded by a prolonged fall in the level of the blood cholesterol; therefore the

reduction in the blood cholesterol in epileptics was not the result of the attack. What the exact relation was between these phenomena they did not know, but the investigation was continuing. He expressed indebtedness to Dr. R. Langdon-Down for much help in connexion with this work. Replying to Dr. JAMES TAYLOR, who said that it was a well known fact that many epileptic women during pregnancy had no attacks, and who asked whether the cholesterol was less or more abundant during pregnancy, Dr. RUSSELL BRAIN said that during pregnancy it was generally regarded as above normal.

Dr. KINNIER WILSON referred to his recent Harveian Lecture (BRITISH MEDICAL JOURNAL, July 3rd, 1926, p. 1), and said that in a paper to be published shortly in the same journal he was dealing with the problems of epilepsy so far as they concerned life assurance; he therefore confined himself to some clinical and physiological points. Epilepsy was certainly not a disease entity but only a symptom; recurrent fits were symptomatic of many different morbid processes, and there might easily be more than one cause of idiopathic epileptic attacks. Epileptic symptoms were not themselves always a sign of disease. Experimental convulsions could be readily brought about in animals which were anatomically and physiologically normal. In many fits, as every clinician knew, movements occurred which were quite ordinary, such as champing of the jaws, smacking the lips, spitting, and clutching. Most of them had seen cases in which not more than one or two epileptic attacks had ever occurred, and to assume that these were due to disease was most questionable. The attack was physiologically only the setting free or loosening of a discharge of accumulated neural energy. Any neural mechanism at any physiological level might be epileptogenous. The crux of the problem concerned the circumstances in which accumulated neural energy was discharged. They did not know what decontrol meant physiologically, nor whether the constellations of neural cells discharged spontaneously or because they were touched by equally unknown effluents. But it was possible to unify to some extent their conceptions of the varieties of epileptic attacks on the supposition that they were due to accumulated static energy manifesting itself in a dynamic form, whatever the structural or anatomical site.

Dr. T. GRAINGER STEWART remarked that they had all, in their practices, seen certain cases which fell into definite groups. There were cases, for instance, in which the association of the attack with certain physical changes was a constant feature. In trying to discover the etiology of epilepsy, he thought it was important to consider epilepsy, not as a disease, but as a manifestation of something abnormal, and to collate certain cases in which similar clinical features and physical changes could be demonstrated throughout the series. Such a group of cases might then form the subject of united investigation. He described one of three similar cases which he had seen and which seemed to belong to a definite group. The case was that of a school teacher who had been exposed to air raids, which possibly might account for a psychical factor. Her family always knew when an attack was pending because of her offensive perspiration. After the development of the attack, instead of being a fresh-complexioned, comely woman, her skin became greasy and blotchy. Her pulse also at these times was abnormally slow, although previous to the development of the attack it was quite normal. He had seen two other cases in which the offensive perspiration, the slow pulse, and the change in the condition of the skin had been associated with epilepsy. Why this occurred, and what was its cause, he did not know, but after treatment with belladonna they made a complete recovery. The longest term for which it was necessary to treat them was six weeks. He could not explain why the belladonna had this effect, but believed that such a group of cases might advantageously be studied and some definite advance be made.

Dr. G. A. SUTHERLAND said that his own problem, like that of others, had been the difficulty of recognizing and diagnosing cases as being really due to epilepsy, and he was afraid he had blundered in classifying as "petit mal" cases which were not due to that condition at all. One matter specially deserved attention—namely, the condition of the circulation, and in particular cerebral anaemia. Gowers and Clifford Allbutt had laid very great stress on the fact in connexion with epilepsy that there were no changes in the circulation. The cerebral attacks in epilepsy were supposed to be due to a sudden "explosion" in the brain cells—that was as good a pathology as any. In circulatory attacks, which were liable to be confused with epilepsy, the heart might be organically sound or it might be diseased, but there was not necessarily any evidence of disease in the patient in the intervals between attacks. Again, just as in epilepsy itself, so in these circulatory conditions, the attacks were of two kinds, one mild, and evidenced by fainting, and the other severe, leading to convulsive movements; both of these were due to cerebral anaemia—it was simply a question of degree. The changes to which he referred might take one of two forms—either an extreme tachycardia or an extreme brachycardia. In the latter condition the attacks were due to the standstill of the ventricle. Mackenzie had said that if the ventricle of the heart remained still for a period of ten seconds cerebral symptoms would predominate; these symptoms might take the form of syncope or they might go on to a form of severe convulsion with stertorous breathing. The other condition was not so well known. Tachycardia took the two forms of paroxysmal tachycardia and, sometimes, auricular flutter. The attack of paroxysmal tachycardia started suddenly, so that the similarity to an epileptic fit was very much increased thereby. This was the type of case in which the diagnosis of petit mal or epilepsy might easily be made. He thought it would be well to look into the question of the circulation during the period of the fits. The heart should be carefully examined to see whether there were any changes such as those to which he had alluded. By paying close attention to the cardiac conditions during fits, a class of fits might be found of which little notice had hitherto been taken, and a wrong diagnosis might be prevented.

Dr. ALDREN TURNER, replying, thought that the arrest of the circulation mentioned by Dr. Sutherland was more probably a consequence of the seizure than its cause. As for the biochemical side of the investigations, he could not satisfy himself that any light on the subject was being obtained from that study. He felt great difficulty also, with regard to the animal experiments brought forward by Dr. Riddoch, in admitting that it was useful to compare the condition in epilepsy with the convulsions induced in animals by injections, and asked whether the experimenter had ever observed on any occasion in these animals recurring attacks of petit mal. Although the major epileptic fits were the more dramatic, petit mal was the outstanding criterion of epilepsy to the physician. Unless Dr. Riddoch had seen recurring seizures of petit mal following these injections, the speaker felt that these animal experiments were of very little value in the study of epilepsy as commonly understood.

SURGERY OF THE COMMON BILE DUCT.

AT a meeting of the Liverpool Medical Institution on December 16th, 1926, Professor R. E. KELLY read a paper entitled "Some observations on the surgery of the common bile duct."

Professor Kelly said that his paper was based on the records of 50 cases in which the common bile duct had been explored; these cases brought to light many interesting conditions. They showed that the common duct might be packed with stones without jaundice, and even without pain; that stones might be found in the common duct together with an enlarged gall bladder; that malignant disease might be associated with attacks of pain and a variation in the depth of the jaundice; that stones might occur with deepening jaundice and no pain; and that malignant disease and stones might be associated. Professor Kelly thought that mere palpation of the common duct was insufficient to give accurate information of the condition of the duct or its contents. He suggested that every dilated common duct should be explored with the finger, probe, or catheter, and that failure to reach the duodenum by these means should be followed by a transduodenal choledochotomy. He discussed the difficulty in

distinguishing malignant disease from impacted stones in the ampulla of Vater. He thought that malignant disease in this situation was very grave, and that reported cures were sometimes due to mistaken diagnoses. With regard to the details of the operation, he had used all the incisions recommended, and for particular reasons liked them all. He thought, however, that in the very obese, with a wide costal angle, the complete transverse incision gave particularly good access and a strong scar. On many occasions he had used the double catheter—one passed upwards into the hepatic duct, and the other down into the duodenum, facilitating the supply of liquid nourishment.

Vital Capacity in Heart Disease.

Dr. WALLACE JONES gave an account of investigations into the vital capacity in heart disease. A simple water spirometer was used, and the readings were expressed as percentages of the standard normal vital capacity calculated by means of West's formula. Fifty normal men and fifty normal women were examined to see how closely the actual vital capacity corresponded with the calculated vital capacity. The result showed that though marked individual variation occurred, the average figure was very close to the calculated normal. In organic cardiac disease there was a marked fall in the reading, the average being between 50 and 60 per cent. of the normal figure. The vital capacity was lowest in the mitral stenosis group, especially when associated with auricular fibrillation. In functional cardiac disease the average reading was 85 per cent.—a very high figure in view of the marked dyspnœa which was generally associated with this condition. A group of cardiac cases was also kept under observation for a considerable time, and though the vital capacity improved with increase in the cardiac reserve power, the readings only followed slowly the changes in the heart condition.

JAMES MACKENZIE INSTITUTE.

AT the James Mackenzie Institute for Clinical Research, St. Andrews, on December 21st, 1926, Dr. WALTER ELLIOT, M.P., gave an address on clinical research in its relation to the public health services. He expressed first his conviction of the valuable results which must accrue from the meeting of public health administrators and general practitioners, and laid it down as a fundamental rule that every respect must be paid to the opinions of those in touch with the living being; the "clinician of the farms" had knowledge with regard to stock unpossessed by many professors. The fact that research figured in the agenda of the Imperial Conference last autumn for the first time in history marked a distinct stage in the attitude of the administration towards it. But there was a danger that too much reliance was being placed upon the word "research," and that anyone getting into difficulties had only to pronounce the magic word to have his difficulties overcome. There was also the danger of clinical research coming to be looked upon as something apart from the practice of medicine, whereas it should grow and flower out of the daily work of practitioners. This required observation, intuition, imagination, just as much in the clinician in his daily round as in the laboratory worker.

In the relationship of clinical research to the public health services there was a danger that the turning on of the enormous machine of administration to the work of people who were "on their own" and unco-ordinated might do more harm than good. One way to avoid this danger was to have a proper conception of the work and difficulties of research, both in the minds of the administrator and of the clinician. The administrative worker must come into contact with the growing process which research represented.

Dr. Elliot summarized his conclusions thus: (1) Public health work would increasingly concern itself with research. (2) Control, especially superimposed control, would of necessity fail, and opportunities for work were the most that organizations could hope to offer. (3) The independence of scientific institutions ought to be jealously guarded so as to provide the necessary check on the rapidly increasing undertakings of State research.

Reviews.

PHYSIOLOGY FOR THE MEDICAL PRACTITIONER.

PROFESSOR J. J. R. MACLEOD of Toronto is to be congratulated on the success of his book, a fifth edition of which is called for since its first appearance in 1918. Although *Physiology and Biochemistry in Modern Medicine*[1] is as admirable as ever, both in its material and its mode of presentation, the serious question arises whether it is as good a book in its present form as, say, the first and second editions. We are of opinion that Professor Macleod has made a mistake in expanding his excellent and original book, designed as it was (to quote from the preface to the first edition) to review "those portions of physiology and biochemistry which experience has shown to be of special value to the clinical investigator. The work is not intended to be a substitute, either for the regular textbooks in physiology or for those in functional pathology. It is supplementary to such volumes." There was a very real need for a book which would interest men whose work lay on the clinical side—a book which would bring before these workers, clearly and definitely, the salient facts of physiology. And now at the behest of "various teachers of physiology" Professor Macleod has been inveigled into changing his outlook, into, indeed, that time-wasting sport of trying to kill two birds with one stone. In the preface to the new edition he states that his "manual has been expanded in the present edition in order that it may also be used as a textbook of physiology for students of medicine." There is enough of the excellent original to the fore to prevent the book from falling between two stools, but, if the aim is to be achieved of making this compendium serve both as a textbook of physiology and a scientific bedside guide in the study of disease, the next edition will require to be expanded still more in order that the pure physiology aspect may be adequately treated. Many of the present stimulating sections, sufficient though they be for the worker who has already studied physiology in one of the standard works, will require drastic alteration and extension if they are to be the sole sources of information, and sundry gaps will require filling. We hope and believe that, for instance, sleep, phonation, and reproduction each and all are still part and parcel of physiology.

Although we regret the alteration in the plan of the book, and believe that Professor Macleod's better judgement will endorse this regret, it goes without saying that the volume is well up to its old standard of interest and information and that it will prove invaluable to the clinician who wants a good working knowledge of modern physiology. The sections on circulation, respiration, and metabolism—except the chapter on dietetics, which is really inadequate—are excellent and stimulating surveys of their respective fields.

MENTAL HYGIENE.

DRS. HENRI BOUYER and MARTIN-SISTERON have written a volume entitled *L'Hygiène Mentale et Nerveuse Individuelle*.[2] Though many works have been devoted to the subject of the prevention of diseases of the body, the medical profession has concerned itself but little with the preservation of the mental health of the community. Twenty years ago Sir Thomas Clouston was responsible for a book in which he endeavoured to utilize our knowledge of the mind and nervous system and their disorders, with a view to developing a science of mental hygiene. Since then the importance of this subject has been increasingly recognized, and there is now a growing body of literature dealing with the application of psychiatric knowledge to the problem of the prevention of mental disorder. The book with which this notice is concerned deals clearly and adequately with the subject, and the student and practitioner will find it useful as a textbook of mental hygiene,

[1] *Physiology and Biochemistry in Modern Medicine.* By J. J. R. Macleod, M.B., LL.D.Aberd., D.Sc.Tor., F.R.S., assisted by Roy G. Pearce, A. C. Redfield, N. B. Taylor, J. M. D. Olmsted, and by *others.* Fifth edition. London: H. Kimpton. 1926. (Roy. 8vo, pp. xxxii + 1054; 291 figures. 42s. net.)

[2] *L'Hygiène Mentale et Nerveuse Individuelle.* Par Dr. Henri Bouyer et Dr. Martin-Sisteron. Préface de M. le Dr. Henri Claude. Paris: A. Maloine. 1926. (5¼ × 7½, pp. iv + 352. *20 fr.*)

for the profession is still in need of further information on this matter. As Professor CLAUDE observes in his preface to this volume, "What examiner in the faculties of medicine dare set a question on mental hygiene?" He insists, furthermore, on the necessity of interesting the medical profession, and all those who believe in the progress of the social organization, in a subject which will one day be regarded as of primary significance. The considerable incidence of mental disorder in the community certainly makes it desirable that no efforts should be spared to bring about its diminution.

ATLASES OF HUMAN ANATOMY.

In *Baillière's Synthetic Anatomy*,[3] by Dr. J. E. CHEESMAN, we have an atlas quite different from those to which we are accustomed. Instead of a series of separate figures drawn to different scales and reproduced on separate pages, Dr. Cheesman has provided a series of diagrams representing the anatomical arrangements of a part as they may be seen, so to speak, in serial longitudinal sections, all drawn to a uniform scale on transparent sheets, capable of being superimposed on each other. In other words, the student can study the anatomy of a part in layers, lifting up or laying down one sheet after another. Further, by looking through the superimposed sheets he can, within limits, study at one and the same time several layers. The figures are necessarily somewhat diagrammatic, or, as Dr. Cheesman prefers to describe them, conventional; for the structures in the various layers have to be regarded as running in parallel horizontal planes, as otherwise it would be impossible to obtain a connected or continuous view of them. The aim has been to give a definite, composite, and stereoscopic mental picture of every region of the body, step by step, and part by part. The atlas will be published in twelve parts, of which the first three, dealing with the upper extremity, are already issued. If we take the part dealing with the shoulder and upper arm as a fair index of what the other parts will be, each part will consist of some twelve figures, most of them coloured. While the idea of the atlas is perhaps not entirely original in every respect—the old "window atlas" in which sections could be lifted up and folded back and so parts underneath exposed to sight might, we think, be regarded as an earlier form—there can be no question that in the hands of Dr. Cheesman the plan has undergone a process of elaboration which makes it in all essentials an original piece of work and one which we think may well prove helpful to the student, particularly in revision, for, as in all atlases, the stereoscopic representation tends to be defective; to obtain a true conception of depth it would appear that there is no substitute for dissection. The atlas is accurate to an unusual degree for a first edition; the figures are not lacking in artistic finish, and the dissections and planes have been chosen with judgement and skill. There have evidently been technical difficulties in the exact application of colour to the blood vessels—difficulties which have not been in many cases entirely surmounted. We consider, however, the atlas a highly commendable production on which both Dr. Cheesman and the publishers may be warmly congratulated. As the price of each part is only half a crown, and as each part can be purchased separately, we have no hesitation in advising any student who experiences difficulty in his study of anatomy to purchase a part and to find out for himself if he receives material assistance—as we think he will—from the method here devised.

The *Atlas of Human Anatomy*[4] by CARL TOLDT inevitably invites comparison with the similar atlas by Spalteholz. Judged by number of pages or illustrations, Toldt's is the larger, and yet it is published in two volumes, whereas Spalteholz's is published in three. Naturally the subjects chosen for illustration are largely identical, but there is a striking difference in the manner of their reproduction, for whereas in Toldt's the figures are line drawings, in Spalteholz's they are half-tone. The atlases illustrate very clearly the advantages and disadvantages of the two methods, the line drawing permitting of much greater detail, while the half-tone, sacrificing a certain amount of detail, succeeds in conveying the clearer conception. There is a danger in line drawings of attempting too much detail, with the result that definition is obscured, if not actually lost, a danger which Dr. Toldt has not always been able to avoid, as, for instance, in the figure, numbered 353, of the calcaneum. The absence of any illustration showing the auriculo-ventricular bundle suggests that the atlas is not in every respect abreast of the times. A certain carelessness is also evident here and there—the crowns of the teeth, for instance, in figure 556. We note, too, a repetition of the error that angulus Ludovici means angle of Ludwig. On the whole, however, the atlas—which must have entailed in its preparation great patience and labour as well as ingenuity—reaches a very high standard of excellence, and the choice between it and Spalteholz's must largely depend on the preference which the student may have for a line or half-tone drawing; it must partly depend, too, on the depth of his purse, for Spalteholz's is more than half again as expensive as that of Toldt's, the result no doubt of the more generous use of colour by Spalteholz.

L'Anatomie en Poche[5] is a small pocket atlas with 297 illustrations—a kind of companion volume in French to the well known Gray's *Pocket Anatomy*. The illustrations, of which many are coloured, follow the usual lines, with, however, a definite bias to the diagrammatic, particularly evidenced in those dealing with the nervous and lymphatic systems. The main advantage of the atlas lies clearly in its size and the consequent ease and frequency with which it may be consulted. The illustrations are on the whole well chosen, clear, and accurate. The book is, we think, likely to prove of assistance to those students who, for one reason or another, find during the day short intervals of leisure, as, for instance, on railway journeys.

LOCAL ANAESTHESIA FOR THROAT, NOSE, AND EAR.

DR. KING has rendered a service of inestimable value, not only to laryngologists, but also to general surgeons who employ local anaesthesia, by setting out in an impartial yet authoritative manner the present position relating to the properties and employment of local anaesthetics.

This occupies about half of his book entitled *Local Anesthesia in Otolaryngology and Rhinology*.[6] The second part of the volume consists of the reports of the committees of the American Medical Association on the toxicity, advantages, and disadvantages of the various local anaesthetics in nose and throat work. This is edited by Dr. Emil Mayer, the chairman of the research committee on local anaesthesia. The third part consists of a folded table, contained in a pocket in the cover, setting forth the details of forty-three cases in which death occurred under local anaesthesia.

The book is worthy of careful and serious study by all who use local anaesthetics; the general conclusion is that cocaine should never be injected, and only applied in weak solutions, but that for injections novocain in dilute solution is both safe and efficient. The great majority of accidents have followed the use of cocaine, and it is worth noting that Dr. Rudolph Matas, the celebrated surgeon of New Orleans, has advised that the use of cocaine should be abandoned altogether. While the recommendations do not go to this length, yet the use of cocaine paste is unsparingly, and as we believe rightly, condemned. The use and value of antidotes and methods of resuscitation are left a little uncertain, but it appears that experimentally the use of calcium salts in cocaine poisoning has no value. It is clear, however, that if the recommendations put forward are universally adopted accidents will almost, if not entirely,

[6] *Local Anesthesia in Otolaryngology and Rhinology.* By James Joseph King, A.B., M.D. New York: Paul B. Hoeber, Inc. 1926. (Med. 8vo, pp. xi + 205; 21 figures. 5 dollars.)

cease to occur, and it is also apparent that accidents, both fatal and also of minor degree, have been far more frequent than the number reported might lead us to assume.

The new anaesthetic borocaine is not mentioned, but apart from this the summary is complete and unbiased. It may be that the ideal agent for local anaesthesia has yet to be found, but for the moment Dr. King seems to have said the last word on this important matter.

SURGERY AT THE SALPÊTRIÈRE.

PROFESSOR A. GOSSET, professor of clinical surgery in the Faculty of Medicine of Paris, and surgeon to the Salpêtrière, has done well to follow the lead of J. M. Charcot, Pierre Marie, and other physicians who have shared the medical riches of the great infirmary with the world, by deciding to bring out *Travaux de la Clinique chirurgicale de la Salpêtrière.*[1] This first volume, in the preparation of which he has been assisted by fourteen collaborators, contains much interesting material, and its 118 well executed figures are in keeping with the character of the text. Of the sixteen articles, Professor Gosset has written the whole or part of five. Together with Ivan Bertrand he describes as gliomas the tumours often pedunculated and commonly arising from the lesser curvature of the stomach, which have been recorded as sarcomas, leiomyomas, or fibromas; as they are especially derived from the sheath of Schwann they are here divided into massive, myxomatous, ulcerated, and pedunculated schwannomas. With J. Charrier and Ivan Bertrand, Professor Gosset records, with a well illustrated account of their histology, two cases of polycystic gliomatous tumours of peripheral nerves. He also writes on choledochotomy for gall stones, with W. Mestrezat, on the nature and mode of formation of "white bile," and on cholecystography with G. Loewy. These three valuable articles on biliary disease are supplemented by Petit-Dutaillis and Mestrezat's critical contribution, fortified by many observations, on hypercholesterinaemia, and on cholelithiasis, in which they show that from a diagnostic point of view this is of very little value. The wide range of activity of the department is shown by the inclusion of J. Magrou's account of tumours in plants, and his record in conjunction with P. Rouché of actinomycosis in a war wound. Radium treatment of cutaneous cancer is regarded by E. Wallon as the most satisfactory method; Francillon-Lobre reports on radium therapy in 155 uterine fibromyomas during the past five years at the Salpêtrière, and P. Rouché and J. Paul contribute their observations on the blood of cancerous subjects after radium treatment. Two unusual cases of interest are published respectively by D. Petit-Dutaillis on intermittent hydronephrosis in a horseshoe kidney, and by R. Soupault and Ivan Bertrand on a thyroid adenoma of the benign chorion-epithelioma type.

There are other attractive articles in this new publication, which will ensure its welcome by scientific surgeons.

DAME LOUISA ALDRICH-BLAKE.

IN his brief preface to a concise biography of *Dame Louisa Aldrich-Blake*,[2] Lord RIDDELL says, "I have tried to show what she was as well as what she did." In this aim he succeeds well, for the reader gets from it a clear conception of a remarkable woman.

Lord Riddell's task cannot have been easy, for written material from which to glean information was scarce, and revelations of an intimate nature were not part of Dame Louisa's habit of mind. Nevertheless, from the dry facts of ancestry, environment, and achievements the author has contrived to create a picture which lives. He compares Dame Louisa to a "stately frigate, which rarely furls its sails, and is set on a steady course through the buffeting waves of life." She led a life internally serene, and externally concentrated on achievement of purpose. In reply to an inquiry from Lord Riddell as to how she succeeded in being so disinterested, she gave this characteristic answer: "Never having been compelled to earn my living, I have been freed from the strivings that inevitably beset the lives of most professional people."

An interesting chapter is that one which contains quotations from Dame Louisa's collection of aphorisms. The address she gave at the School of Medicine for Women in 1900 sets forth her philosophy, and is quoted at some length. "No man is a hero to his own valet," but many greater folk might well envy the unspoken testimony in the bare statement made by the author that Dame Louisa's maid was with her for twenty-five years, and in the note of true devotion sounded by her chauffeur in his description of the final journey to Bicknor.

THE WAR HISTORY OF THE UNITED STATES ARMY MEDICAL DEPARTMENT.

THE medical history of the United States Army in the great war is being published at intervals as each subject is completed for the press. Thus the first volume to appear was the last of the scheduled series—namely, Part I of Volume XV, containing tables of anthropological measurements of recruits. It came out in 1921, and no other volume was published until 1923, when Volume I on the administrative work of the Surgeon-General's Office in Washington and Volume V on the military hospitals in the United States were issued. These were followed in 1924 by Part II of Volume XI on surgery, in 1925 by Part II of Volume XV on casualty statistics, and more recently by Volume VIII on field operations. Only one-third, therefore, of the complete series has so far been published. In this connexion it may be recalled that the eleven volumes of the comprehensive British medical history of the war were completed in 1923, and that by the end of that year all but the last two, which did not emerge from the press until early in 1924, had been published.

Volume VIII of the United States history[3] is a massive volume of 1,097 pages, and is the equivalent of the four volumes of the general history of the British medical services, whose arrangement it follows closely. The first section, on field operations, gives a general account of the United States medical organization and of its medical units in the field, together with a brief chapter of less than three pages on the veterinary service, which came under the administration of the medical department in 1916. Section II deals with the work of the American divisions incorporated in French armies during the operations subsequent to the German advance in 1918 south of the Somme, and during the operations on the Aisne and Marne, which inaugurated the allies' advance to victory. It was not until after this phase of the war that the American Expeditionary Force was in a position to concentrate as an army on its own front and with its own lines of communication. The U.S.A. First Army was then organized in August, 1918, and in the middle of September was allotted the task of carrying on operations on the St. Mihiel front and in the Meuse-Argonne sectors. The work of its medical services during these operations is recorded in Sections III and IV of the volume. The Second U.S. Army was organized in time to take over the St. Mihiel front from its First Army before the armistice, but made no active advance until three days before the cessation of hostilities. Its operations, together with contemporaneous operations of certain American divisions with French armies in Champagne and Flanders, are described in Section V. The next section is a single chapter on the training of the U.S.A. Second Corps with the British Second Army and the subsequent activities of the corps with our Fourth Army during the advance to victory. The final section of the volume contains chapters dealing with the occupation of Germany after the armistice by the U.S.A. Third Army, which had been in course of preparation, and with an account of American medical services in Italy, North Russia, and Siberia. The last hundred pages form an appendix containing brief histories of each division

[3] *The Medical Department of the United States Army in the World War.* Volume VIII: Field Operations. Prepared, under the direction of Major-General M. W. Ireland, by Colonel Charles Lynch, Colonel Joseph H. Ford, and Lieut.-Colonel Frank W. Weed. Washington: Government Printing Office. 1925. (Sup. roy. 8vo, pp. 1097; 23 tables, 4 charts, 60 plates, and 99 figures: 3 dollars.)

the field, extracts from field service regulations and the manual of the medical department, and tables of organization of the United States Army.

It is not possible to examine critically, or to do full justice to, a volume of this kind in a review of the length possible to us. Generally speaking, the medical experiences and the lessons learnt from them are similar to what has already been recorded in the British official medical history of the war. The Americans appear to have been in a constant state of anxiety on account of shortage of medical personnel. In one place it is stated that the armistice was the only thing that saved the medical department from disastrous situation because of this. Yet at that time the U.S.A. medical services had 30,591 medical officers and 81,341 enlisted men. With these enormous resources, more than double those of the British medical services for a much larger force and employed over a much longer period of time and in more varied and wider fields of war, one can only surmise that, if there was so serious a shortage, the personnel could not have been distributed economically. The number and variety of specialists and specialist teams also appear to have been a distinct drain not only on personnel but also on transport and equipment. Specialists were to be found in every zone of operations in the field, and we read of surgical, orthopaedic, psychiatric, tuberculosis, urological, and gas treatment experts in divisional triage stations, and even in advanced dressing stations. Also, on more than one page, the multiplicity of clearing and special hospitals is noted as causing confusion and wastage of personnel and transport.

The printing, illustrations, and maps in Volume VIII are beyond praise, although some of the maps are too crowded with detail to make it possible to follow them with ease. As a book of reference and study for British readers it will prove a useful supplement to the British medical history of the war, as in many respects it confirms and emphasizes several of the lessons we had already learnt before our American colleagues came on the scene. The price, it may be noted, is exceptionally low for a work of this kind.

NOTES ON BOOKS.

DR. F. H. RICHARDSON finds that, notwithstanding the flood of books on what is called the new psychology, it is not easy to find concrete suggestions for parents on the management of the early years of childhood. He has endeavoured to supply the want by his *Parenthood and the Newer Psychology*,[10] wherein he aims at setting forth the cardinal principles of this psychology, and at applying the principles in such a manner that the parent shall better understand his child. His chapters inform us that the greatest thing in the world is love; that the greatest danger in our lives is arrested development; that the strangest thing in the world is our consciousness; and so on. The greatest opportunity ever offered is said to be the education of a child. This appears to be an arduous task, and it is surprising that the American father can find time to do it. He must visit his child's school, not once, but several times each term, as a leisurely observer of the pabulum with which his child is being fed. Mentally he must place himself in positions similar to those in which his child is being put, in order to judge of the situation. If he finds the teacher's explanations muddled, and if he evaluates properly the feelings of his son, he must begin to look about him for a better school, and be prepared, if necessary, to dispense with a much-loved motor car or a highly prized style of living in order to obtain better educational facilities.

The second part of the third volume of the system of medicine,[11] edited by Professor G. VON BERGMANN and R. STAEHELIN, is devoted to diseases of the alimentary system. Affections of the liver, bile ducts, and pancreas are discussed by Dr. Friedrich Umber of Berlin, who prefaces his clinical study by remarks on the development, structure, and chemical composition of the liver. A bibliography of ten pages is appended in which British names are conspicuous by their absence. The chapter on the diagnosis and treatment of intestinal diseases in general is written by Professor F. Seiler of Berne. To the first part of the fourth volume Professor Paul Morawetz of Leipzig and Dr. Gerhard Denecke of Marburg contribute an article on the blood and its diseases, including a consideration of its physiological chemistry and methods of clinical examination. Professor Felix Lommel of Jena writes on diseases of muscles, bones, and joints, Professor Max Klotz of Lubeck on rickets, and Professor W. Alwens of Frankfort on late rickets, osteomalacia, senile osteoporosis and osteopathies due to starvation. Professor Leopold Lichtwitz is entrusted with the section on diseases of metabolism, including diabetes mellitus, gout (in which he has the collaboration of Dr. Steinitz of Hanover), obesity, malnutrition, and various anomalies of the urine. An appendix contains an article by Dr. Erich Meyer of Göttingen on diabetes insipidus. The book is a laborious compilation which will no doubt be found useful for reference.

Hygieia, or Disease and Evolution[12] is Dr. BURTON PETER THOM'S contribution to the To-day and To-morrow Series of Messrs. Dutton of New York. Though Dr. Thom is not a very clear exponent of his object, we gather that he is a convinced optimist. The disease factor in evolution has, he thinks, two aspects—the biologic and the sociologic. Diseases not only eliminate the unfit; epidemics may be a further blessing in disguise by acting as milestones in the progress of humanity. Thus, according to Dr. Thom, the Black Death more than anything except the advent of Christianity broke the power of the strong over the weak, and inaugurated the glorious era of industrialism w[illegible] the earth and all that dwell therein. [illegible] beneficial work, disease will ultimately disappear, and the prohibition of alcohol, it is held, will help its disappearance, and assist in the advent of the golden age when misery will be no more, and peace, health, and happiness will reign supreme.

In their *Health Visitor's Guide*[13] the Misses ASHBY and EARP state that there should always be a period of at least two years between the birth of one child and the next, thus effectively eliminating any more families of twenty. They advise scrubbing the nipples with a nail-brush to make them tough and supple; and they quote, apparently with approval, a child who, when asked to play a game, said, "No, I have been naughty; I must stand in the corner." Apart from such slight eccentricities their little book is a useful compendium for the health visitor, and may help, as suggested in the preface, to condense and "pigeon-hole" her knowledge.

The aim of *Baillière's Nurses' Complete Medical Dictionary*,[14] edited by Dr. H. CLIFFORD BARCLAY, is to fulfil at once the purpose of a dictionary and an encyclopaedia for nurses. The present edition contains a number of new words dealing with the subjects of electricity, midwifery, ultra-violet rays and *x* rays, and contraception. The work as a whole fulfils a useful purpose, but is sadly in need of revision. In addition to the presence of many words not in common use we have noted several errors, such as "empyaema," "labium minor," and "a white striae," as well as the statement that Koplik's spots are found in anaemia and are caused by the Leishman-Donovan parasite, that typhus comes from flea-bites, and paratyphoid is caused by the paracolon bacillus.

The Nursing Mirror Pocket Encyclopaedia and Diary, 1927,[15] is the result of a thorough revision of previous issues, while several new subjects have been introduced. This handy book is constructed on most practical lines, and will be found very helpful as a pocket reference guide for most contingencies that are likely to be encountered in nursing. The alphabetical arrangement of the contents and the careful attention paid to separating clearly the various paragraphs facilitate quick reference.

DR. CARL POROTZKY'S book on gymnastics for nervous children[16] is intended for doctors, teachers, and parents; it consists of a brief description of thirty-nine exercises, each of which is accompanied on the opposite page by an excellent photograph of the child engaged in its performance.

PITFALLS IN DIAGNOSIS.

ADDRESS BY PROFESSOR FINNEY OF BALTIMORE.

DR. J. M. T. FINNEY of Baltimore (Professor of Clinical Surgery, Johns Hopkins University) addressed the Post-Graduate Hostel, at the Imperial Hotel, London, on January 18th, and the Section of Surgery of the Royal Society of Medicine on the following day. In both cases the announced subject was "The pathology and diagnosis of gastric and duodenal ulcer," but in addressing the post-graduate audience Dr. Finney took a wider range, and spoke of pitfalls in making a diagnosis in abdominal conditions generally. He adopted as his "text" the title of a book recently published in the United States by a well known war correspondent. The title was "Concerning the operation," and the book was written during the convalescence of the author, and contained some reflections which Dr. Finney found more thought-provoking than complimentary.

Diagnosis, said Dr. Finney, was sometimes spoken of as if it were a routine matter—as though any fool could make it. He himself, however, found great difficulty in reaching a positive conclusion, even with the best help he could obtain from instruments of precision. Some surgeons were accustomed to inveigh against the physician on this matter of gastric ulcer, saying satirically that the ulcer had been "cured" medically half a dozen times already. Well, perhaps it had, perhaps it had not. One surgeon in the States was accustomed to say, with a wave of his hand, "The aseptic scalpel is the absolute panacea for all surgical ills." That sounded well; it caught the gallery. But what about the percentage of mortality in every surgical operation? Even in the best hands, under the best conditions, in the best hospitals, there was an appreciable mortality rate in surgery, also an appreciable percentage of unsatisfactory results after operation. It puzzled him to hear surgeons claiming 100 per cent. of cures for a given procedure.

In certain cases, even with the most skilled help, it was necessary to make an exploratory incision in order to ensure the diagnosis. With the open abdomen the surgeon was dealing no longer with a theory, but with a condition. In the absence of some definite, demonstrable pathology he found himself closing the abdomen again, and he thought that was good surgical judgement. It seemed to him that most of the bad results in surgery were due to the non-discovery of a definite pathological condition at the time of operation. Given the definite pathological diagnosis, the rest was easy. The actual art of surgery was a thing that almost anybody could acquire. It was a question of manipulative skill and of sufficient experience as a result of repeated operations. But surgical judgement was the rarer thing. It was not altogether intuitive—though some people seemed naturally to do the right thing—but most of it was just downright hard work, careful observation, and the exercise of one's reasoning capacity.

Dr. Finney was specially impressed with the difficulty of differentiating between a variety of possible things in dealing with abdominal conditions. Some years ago he was called out into the country to see a young girl who had pain in the stomach, vomiting, and so forth, and whose case, from the description, looked like a typical appendicitis. But after a close examination the only thing he was sure of was that this was not an acute appendix. The country doctor in charge of the case asked him what he was going to do, expecting him to do something. He replied that if he had the girl in hospital at Baltimore he would not operate. But he was compelled to return to Baltimore, and was begged to do something before he went. The case was put to the girl's parents, who were sensible folk, and they said, "Would it not be safer to take the appendix out?" Rather against his better judgement he took the appendix out, and found, as he expected, nothing there to account for the condition. Returning to Baltimore, he received next day a laconic telegram from the doctor; it read simply, "Measles"! Every surgeon must have seen these abdominal cases, looking very much like appendicitis, in association with certain of the acute exanthemata, probably arising from some form of congestion. Shortly after this case he was called to see a child in Baltimore with a similar condition. With this experience fresh in his mind, and as the characteristic signs of an acute appendix were not present, he asked casually whether any measles were about, and learned that actually there was a case of measles in the same house. This case, again, proved to be measles; but, just to show how fatal it was to argue from one case to another, he was called shortly afterwards to another case presenting similar features, and on the strength of this experience he suggested measles; at two o'clock the following morning he was summoned by telephone to perform an operation for acute perforated appendix. The whole point of the matter was not to be too cocksure about diagnosis. It was better to have an open mind and the humble sense of being human and prone to mistakes.

Many years ago, before the x rays were available, he was called to see a boy who was suffering from severe abdominal pain and upset. It appeared that he had been eating nuts. Sir William Osler, who was in Baltimore at that time, used to say that every circus that came to town brought an epidemic of appendicitis owing to the consumption of peanuts and circus lemonade by the juvenile community. There appeared to be reason to suspect appendicitis in this case. But when Dr. Finney was sent for to operate he refused to accept the ready-made diagnosis. He satisfied himself that this boy had not acute appendicitis. One feature of the case was that the boy insisted on lying with his thigh curiously flexed, maintaining this position day after day. He thought of hip disease, of everything except the right thing. The boy had no local abdominal signs, though he insisted that his pain was abdominal. Sir William Osler was asked to examine him. By that time the boy had developed a cough, and as there was a history that he had visited a house in which there were several cases of typhoid fever, Osler, with this in his mind, said that it looked like an atypical typhoid, but beyond that he would not commit himself. Other diagnosticians were called in, but without result. Not until a week afterwards did the true condition reveal itself. It was an acute osteomyelitis in the ilium, and the pain had been referred to the abdomen. By that time the condition was septic, and although an operation was done, the boy died.

In diagnosis and in choice of operation also it was very important not to go upon preconceived ideas. Nothing militated so much against success. To determine the best thing to do, once the condition was diagnosed, was not a rigid matter at all; the whole of one's judgement had to be bent to the particular case in hand. There was no one surgical procedure which was applicable to all cases. The choice of procedure must depend upon the surgeon's judgement, experience, and observation of his own previous work and of the work of others. In gastric ulcer, for example, if the surgeon accepted the view, which was held by the Mayo Clinic, that 70 per cent. of gastric ulcers developed cancer, he was not doing his duty to his patient unless he did a wide resection. If he held that the proportion of cases in which this eventuality occurred was smaller, then the question arose whether one was justified in sacrificing so large a proportion of a vital organ like the stomach to relieve what might be an innocent ulcer. That was a question which would be answered by one man in the affirmative and by another in the negative, but the important thing was for the surgeon to have a reason for the operative course he followed—gastro-enterostomy or any other—which he could successfully defend against anybody except the fanatic. One famous surgeon in the United States, Murphy, was fond of using two words, which, Dr. Finney thought, ought never to be used in surgery—the words "always" and "never." Surgery was not as easily predictable as all that. If a thing was said "always" to happen, there would be found to be occasions when it did not happen; if it was said "never" to happen, it would be found happening. He begged surgeons to work out a philosophy in all these matters, and above all things to remember that every unnecessary operation was a reproach to surgery.

SMALL-POX IN THE NORTH OF ENGLAND.

OWING to the large number of cases of small-pox reported lately, both from Sheffield and the district around and from the county of Durham, we have thought it well to seek authoritative information on the spot. For the particulars given below we are much indebted to Professor F. E. Wynne, medical officer of health for Sheffield, and to Professor T. Eustace Hill, medical officer of health for the county of Durham. It will be seen from this general survey of the progress of the epidemic that, while there has been a very considerable prevalence of small-pox in both areas, the cases have been mild, and delay in diagnosis from this cause has favoured the spread of the disease.

THE SITUATION IN SHEFFIELD.

Sheffield was free from small-pox from 1910 until 1922, when eleven cases were discovered and dealt with between April and June. This outbreak appeared to be controlled by a very drastic policy of isolation and vaccination of contacts and a strict search for possible cases in the neighbourhood. Small-pox, however, was prevalent in adjoining areas in Nottinghamshire, Derbyshire, and Yorkshire. In 1923 three cases were discovered, followed by four in 1924. All of these cases were typical of the very mild type which has recently become familiar. A few had well developed eruptions, quite characteristic of the old type of small-pox, but even these cases escaped without any constitutional disturbance whatever.

On October 6th, 1925, a case was discovered in one of the elementary schools. This case was traced through a series of unrecognized cases to two boys who had been in contact with small-pox at Middlesbrough in June, and had there contracted the disease. Their illness had been regarded as chicken-pox; no doctor had been called in; they returned to Sheffield early in July, and before the end of the year forty-four cases had been notified. It was evident that the city was faced with the possibility of an outbreak on a large scale, and a hutment camp at Redmires was taken over from the Education Committee and equipped as a small-pox hospital. During the early months of 1926 the epidemic lingered on, but it was still possible to isolate all contacts in the houses retained by the corporation for this purpose, and in the summer months there seemed to be ground for hope that the epidemic had been overcome. In October of last year, however, the notifications began again to rise rapidly. The total number of notifications in 1926 was 163, of which 107 were made between October 1st and December 31st. For the first fortnight of the present year the notifications have been as follows: Week ending January 8th, 20; week ending January 15th, 157.

The resources of the city are now strained. It is not possible to remove all cases on the day of notification, and a large number of contacts are isolated in their own homes and are suffering serious inconvenience. The accommodation at the Redmires camp is being increased immediately up to 300 beds, and arrangements are in hand for the erection and equipment of further huts at once. Additional staff for the medical officer of health and the medical superintendent of the hospitals has been provided, and will be increased if necessary.

A campaign in favour of vaccination has been instituted in which the Sheffield press has cordially and most warmly co-operated. Thanks very largely to the four Sheffield newspapers, many thousands of persons in the city are being vaccinated or revaccinated. Public vaccinators and insurance practitioners are finding grave difficulty in coping with the demands made on their services. On Friday last, January 14th, a case of concealment of the disease was successfully prosecuted by the town clerk on the advice of the medical officer of health, but there is no doubt that other misdemeanours of this sort are occurring, which cannot always be detected or "proved."

From the medical point of view the most important fact is that while the majority of cases continue to be of a very mild type, often presenting some difficulty in diagnosis, there is now nearly always a history of symptoms at the stage of onset which are very marked and generally diagnosed as "influenza." This did not occur in the cases seen in 1922-24. Again, a considerable number of the cases seen in 1926 and in the first two weeks of the present year have not only had quite serious constitutional symptoms, but characteristic and severe skin lesions, some of which will probably lead to permanent disfigurement. All of these more serious cases are directly traceable to cases of the very mild, so-called "alastrim" type. There has as yet been no fatal case in Sheffield, though there was one in Mexborough, closely adjoining, and others recently elsewhere.

The situation at present is causing great concern to the Sheffield civic authorities, as it affects not only the health but the commercial prospects of the city. Neither effort nor money is being spared, and the health department is working in close co-operation with the Ministry of Health.

SMALL-POX IN DURHAM COUNTY.

The present epidemic of small-pox in the county of Durham may be said to have started in the early part of 1925. During the two previous years cases of small-pox occurred in a few districts; thus in 1923 there were 23 cases in the borough of Stockton, but the disease was stamped out by the second week in July, after which no cases occurred in the borough up to the end of the year. During the last quarter of 1923 an outbreak occurred in the Southwick urban district, adjoining Sunderland, and in the colliery village of Castletown, adjoining Southwick, 11 cases being reported from these two areas, but these two outbreaks were effectively dealt with, as is evidenced by the fact that no cases occurred in Southwick or the Sunderland rural district during 1924. Altogether 37 cases were notified during 1923, and 3 of them were probably not cases of small-pox. In the following year 21 cases were notified, 6 of them being in the Billingham urban district adjoining the borough of Stockton, while there were 4 cases in each of the boroughs of Durham and Stockton and 2 in the Stockton rural district. There is no doubt that the infection during 1923 and 1924 in the borough of Stockton and adjoining districts was the result of infection carried from Middlesbrough, on the other side of the Tees, where small-pox had been seriously prevalent. During the last quarter of 1924 there were only 3 cases in the whole of the administrative county.

During the first quarter of 1925 16 cases were notified in the administrative county, of which 8 were in Billingham, 4 in Brandon, and 3 in Annfield Plain, but these small outbreaks were effectively dealt with, for no cases were reported either from the Billingham or Brandon urban district during the last six months of 1925, and the last case in the Annfield Plain urban district during that year was in July. During the second quarter of 1925 there were 79 cases notified from the administrative county, the largest number of centres of infection being in the north-west of the county—namely, the urban districts of Blaydon, Leadgate, Ryton, Stanley, and Whickham, from which districts 32 cases were notified. For some time previously small-pox had been prevalent in certain districts in Northumberland, adjacent to the north-west boundary of Durham, and there appears to be very little doubt but that the infection of small-pox was carried across the border into these districts in north-west Durham, facilities for such spread being increased by the fact that in Northumberland a number of cases occurred which were not treated as small-pox, and there was also inadequate hospital accommodation for the isolation of such cases. During the same quarter there was an outbreak in a village in the Auckland rural district, 18 cases in all occurring during a few weeks, the spread of infection in that village being undoubtedly due to the first cases being treated as influenza and not recognized as small-pox. During the third quarter of 1925 the prevalence of small-pox considerably increased, almost entirely in districts in north-west Durham, 53 cases being reported from the Blaydon urban district, 27 in the adjoining Ryton urban district, and 23 in the Stanley urban district; while there were also 14 cases in the small Leadgate urban district, 8 cases in the Consett urban district, and 4 in the Benfieldside urban district, all situated in the north-west of the county. During the fourth quarter of

1925 the disease became seriously epidemic, and 729 cases of small-pox were notified, 357 of these being in the Blaydon urban district, 52 in the adjoining Ryton urban district, and 17 in the Whickham urban district. The disease also became seriously prevalent in Chester-le-Street and in the populous rural districts of Chester-le-Street, Easington, Houghton, Lanchester, and Sunderland. The total number of cases notified during 1925 in the administrative county was 976, and in addition there were 91 cases notified in the county boroughs, Gateshead 44, West Hartlepool 32, South Shields 10, and Sunderland 3; Darlington being the only county borough which was free from infection during the whole year.

During the whole of 1926 the disease was seriously prevalent in practically all the populous areas of the county during some part of the year, and cases occurred in every one of the forty-five sanitary districts with the exception of the borough of Stockton and the urban district of Barnard Castle. During the first quarter of the year there were 1,349 cases, of which 338 occurred in the Blaydon urban district, while over one hundred cases were reported from Chester-le-Street (175), Easington (157), and Houghton (103) rural districts. There were also 192 cases notified in the Gateshead county borough, and 172 in the South Shields county borough during the quarter. During the second quarter of 1926 there was a slight decline in the notified cases to 1,200, only 53 cases being reported from Blaydon, but the epidemic was marked in the urban districts of Brandon (89), Hetton-le-Hole (122), Stanley (200), and in the Lanchester rural district (128); while 64 cases were reported from the Gateshead county borough and 170 from the South Shields county borough. During the third quarter the number of cases notified in the administrative county declined to 800, only 19 cases being reported from Blaydon, but there were 118 in Hetton-le-Hole, 144 in Stanley, and 148 in the Easington rural district. Cases were also reported from all the county boroughs, the greatest incidence being at Gateshead (51) and at South Shields (35). During the last quarter of 1926 the epidemic took on much more serious proportions, 2,445 cases being reported, of which 558 were in the Brandon urban district, 145 in Crook, 171 in Hetton-le-Hole, 156 in Jarrow borough, 99 in Shildon, and 147 in Willington, while there were 304 cases in the Lanchester rural district, 188 in the Chester-le-Street rural district, 174 in the Easington rural district, and 164 in the Sedgefield rural district. Cases were reported from all the county boroughs, those with the greatest incidence being Gateshead with 129 cases and South Shields with 25 cases.

The disease during the whole period of its epidemicity in Durham has been generally of an extremely mild type with very few deaths. Although there were 5,794 cases notified during 1926, the total number of deaths registered in which small-pox was given as a primary or secondary cause was only 11, and during the last quarter, when 2,445 cases were notified, there were only 2 deaths in the administrative county, and in both of these small-pox was given as the secondary cause of death.

This very mildness of the disease has led to its spread in two ways; first, it has been extremely difficult to persuade the community of its seriousness, and it was not uncommon for people exposed to small-pox to state that they did not mind if they contracted the disease as they would be able to get a few weeks' treatment in a comfortable hospital with plenty of food, and very numerous instances have come to hand where there has been absolute neglect of precautionary measures on the part of individuals and families. Secondly, the disease was spread in a number of districts owing to the illness not in the first place having been diagnosed as small-pox, numerous cases having been treated as chicken-pox or influenza until suspicions were aroused as to the true nature of the epidemic.

Undoubtedly the spread of the disease has been facilitated also by the unvaccinated state of the large majority of the people in the county, and almost without exception those infected by small-pox had been either unvaccinated or else have been adults who have only been vaccinated in infancy. Moreover, even in districts where small-pox has become epidemic, there has generally been a great reluctance on the part of the people to take advantage of the protection offered by vaccination. It is very probable also that social conditions associated with the prolonged coal dispute have been a factor in the spread of the disease.

Although at the time that small-pox first became prevalent there was in every sanitary district special hospital accommodation for small-pox cases, over 200 beds being available, there have been times during 1926 when the accommodation proved itself to be quite inadequate for the prompt isolation of cases, in spite of the fact that considerable extensions in small-pox hospital accommodation was provided in a number of districts, and that two hospitals which had been used by the county council for the treatment of tuberculous cases, with accommodation of approximately 50 beds, were handed over to the district sanitary authorities for the treatment of small-pox. There has generally been a pooling of the small-pox hospital accommodation throughout the county, and in addition large numbers of cases have been isolated in the small-pox hospitals at Newcastle-on-Tyne, Middlesbrough, and Darlington, as a result of willing co-operation by the authorities concerned, and a large number of cases are still being treated in these hospitals outside the administrative county.

With the object of assisting the district sanitary and small-pox hospital authorities the Ministry of Health, with the consent of the county council, has issued regulations under Section 2 of the Public Health (Prevention of Disease) Act, 1913, as amended by Section 61 of the Public Health Act, 1925, empowering the county council, in certain circumstances, to provide additional small-pox hospital accommodation, and these regulations came into force in the early part of this year.

Although a large proportion of the population of Durham county is still unprotected by vaccination, there has, during the last eighteen months, been a large increase in the number of persons vaccinated. If the population could be brought to realize the absolute protection afforded by efficient vaccination the epidemic might be stamped out in a very short time, and the great financial loss, not to mention the suffering involved, brought to an end. It is estimated that each case of small-pox costs local authorities something between £10 and £12 per case in isolation, disinfection, etc., which means that during 1926 the cost of the small-pox epidemic to the district sanitary authorities has been at least £60,000.

It is interesting to note that in the Blaydon urban district, which, as the figures in this report show, was the original storm centre of the epidemic, the disease has apparently been stamped out, as not a single case was notified during the last quarter of 1926; while from the adjoining Ryton district there has not been a single case notified during the last six months of 1926.

The epidemic has been a great strain on the public health officers throughout the county, and it can be said without hesitation that, generally speaking, the spread of the disease has not resulted from any laxity on the part of those officers. Conferences of medical officers of health and medical officers of hospital authorities were held in May, 1925, and again in December, 1926, and various resolutions were passed, which were forwarded to, and considered by, the district sanitary authorities of the county of Durham. One of the resolutions passed recommended the compulsory notification of chicken-pox, which now operates throughout the county, and at the meeting held in December, 1926, the following resolutions were passed:

1. That in the opinion of this conference the present epidemic of small-pox would not have occurred if the stringency of the Vaccination Acts had not been weakened, and that prompt vaccination or revaccination of susceptible persons is of the utmost importance if the present epidemic of small-pox is to be brought under early control; and that if such vaccination or revaccination was secured small-pox in the county would be stamped out within three months.

2. That in the opinion of this conference hospital authorities of districts where the available accommodation is inadequate for the prompt isolation of all cases of small-pox should utilize, as a temporary measure, their ordinary isolation hospitals for the treatment of small-pox, where such hospitals are suitably situated for the purpose, and make arrangements with adjoining sanitary authorities for the treatment of their ordinary infectious cases in the adjoining hospitals, a pooling arrangement being instituted both as regards the isolation of cases of small-pox and cases of ordinary infectious diseases.

3. That if in any district there is available accommodation for small-pox cases in convenient empty buildings, arrangements should be promptly made for the use of these buildings for the isolation of small-pox cases; and that local hospital authorities should also consider the advisability of at once erecting temporary hospital accommodation to enable them to promptly isolate all cases occurring.

4. That the medical officer of health for each sanitary district should communicate with every medical practitioner in his district, calling his attention to the urgent importance of keeping a careful look-out for all suspicious cases of rash and of at once acquainting the medical officer of health of such cases, and that a copy of the monograph of Dr. McConnel Wanklyn, entitled *The Accurate Diagnosis of Small-pox*, should be issued by the medical officer of health of each sanitary district to every medical practitioner practising in that district.

5. That this conference urges upon the Ministry of Health the importance of amending the Vaccination Acts with the object of making vaccination more general and efficient, as vaccination affords the quickest, most scientific, and most economic means of preventing and arresting outbreaks of small-pox.

6. That a copy of the report of this conference be sent to the press, all medical officers of health of counties and county boroughs, the British Medical Association, and the Society of Medical Officers of Health, urging their unanimous support to the resolution relative to vaccination.

THE DRIFT OF MODERN ANTHROPOLOGY.

BY

SIR ARTHUR KEITH, M.D., F.R.S.

IT is useful for medical men to keep in touch with what is happening in the anthropological schools of Europe, for if anthropologists know their business and pursue it, what they teach as a theory in one year is not unlikely to become the basis of political practice in another. The political, or rather the economic, bearing of anthropology is very evident in the work which Dr. Walter Scheidt has written to serve as a general introduction to the study of human races.[1] The author is one of the younger anthropologists who have been bred in the schools of Munich and of Freiburg; for them evolution is not a dead process, one concerned in shaping human races which lived long ago and far away, but a very living thing, and is now determining the destinies of the nationalities of Europe. Dr. Scheidt and his colleagues regard evolution as a reality, and they are making it their business to find out how evolution in its widest sense is working out its ends under the conditions of modern civilization. Dr. Joseph Deniker's treatise[2] is of another kind; it is a clear exposition of all that relates to the identification of human races, to their distribution and to their ways of living. Anthropology is treated in this French treatise as if it were an academic discipline and had no ultimate bearing on human thought or action. Both of these works, in their respective ways, will provide their readers with an introduction to the wide and systematic study of anthropology; but for those who are about to begin this study Dr. Dahl's simple and living observations made on natives of the Australian bush[3] may serve their purpose better than the two more ambitious and systematic treatises.

To-day Dr. Dahl is the leading authority, not only in Norway, his native country, but throughout the world, on all that relates to the breeding and habits of fishes, but thirty-four years ago he was a young graduate, and had then placed at his disposal, by a generous fellow countryman, a sum of money which permitted him to spend three years in collecting natural history specimens. Two of these years were spent in Arnhem Land, the most northern part of Central Australia, where he made the acquaintance of other hunters and collectors, the native blacks. He spent month after month in their company gathering specimens and noting with a sympathetic and understanding eye their aptitudes and mode of gaining a subsistence. His book is an account of what he did, saw, and thought during these two years, and although it has only now appeared in an English dress, the original was written in Norwegian so long ago as 1897. It is the kind of book which will never grow old, and is a welcome addition to instructive books of travel.

Dr. Dahl describes the natives as "gatherers, catchers, and capturers"; they loved comfort, yet rarely erected a shelter; they enjoyed the warmth which clothing gives, yet never made it; they saw men sow and reap, but refused to copy them. Yet they had to labour harder and longer to obtain a bare subsistence in the "bush" than the Chinese gardeners who supplied Port Darwin with its vegetables. A little picture drawn by Dr. Dahl gives an intimate glimpse of what a primitive life means. He stepped from his tent one morning, having enjoyed a breakfast of damper, ham, and coffee, and had not proceeded far when he came across a native, also at breakfast. The native held in his hand, not a spoon, but a digging stick, wherewith he was laboriously searching for a sufficiency of earth nuts to provide his morning meal. It is well to realize what "primitive life" signifies before we praise it unduly. Another observation by Dr. Dahl helps us to explain a matter which often puzzles students of modern civilization. Less than two hundred generations back our ancestors lived much as those blacks do now, and yet we find among us individuals who are endowed with all the qualities which go to make excellent clinicians. Dr. Dahl's description of how a native hunter sets to work when he wishes to discover whether or not a hollow tree holds an opossum helps us to understand the form in which our clinical abilities had their earliest manifestation. Dr. Dahl observed that the hunter first percussed the trunk and noted the sound emitted; if still in doubt he placed his ear against it and listened; if still unsatisfied he took a long wand, and, wetting the point, climbed the tree until he reached an opening in the trunk, where he thrust in the wetted point of the wand. If on withdrawing the wand he found opossum hair sticking to it, or if it smelt of that animal, then he knew his prey was within, and at once, with his stone knife, took surgical measures for its exposure and capture. A century ago Laennec applied these old-world hunting methods to the human chest, and was acclaimed a discoverer. Modern genius is often a mere perversion of a primitive ability. One is very apt to underestimate the mental outfit needed for leading a primitive life. Most of us, even if we can swim and dive, would be at a loss to know how to recover a 60-lb. turtle which we had seen disappear in the depths of a pool. Yet the Australian black knows how to do it. On diving and reaching his booty he simply turns the carapace with the head of the animal upwards; whereupon the turtle, having to follow its head, makes for the surface, and once upon the surface all that the swimmer has to do is to keep his captive's head turned shorewards, where both arrive in due course. All great inventions are simple when we know how they are made. The native who discovered the management of turtles in deep water had a brain of a high order.

Dr. Dahl asks a question of the greatest interest to everyone, and returns an answer which, I think, most students of mankind will accept as true. Are the aborigines of Australia what they are for lack of opportunities, or are they what they are because of their mental outfit? Dr. Dahl sums up the evidence, and comes to the conclusion that it is not possible, by any process of education whatsoever, to convert an aboriginal tribe into a civilized community. Dr. Scheidt, if he knew of Dr. Dahl's opinion, would agree with it, for he realizes that we who form the nationalities of Europe come of an ancestry which has been sifted in the sieve of civilization for some two hundred generations; those ancestors whose mental abilities and proclivities fitted them for the restrictions and discipline of civilization have come through the meshes of the selective sieve; the families and breeds which refused to bend their necks to the yoke have been rejected and thus eliminated. If an aboriginal population is to become fit to live our lives it must do what our ancestors have done—go through

the sieve of selection for hundreds of generations. Dr. Scheidt is fully alive to the importance of Darwin's law of selection; but he lays even greater stress on Count Gobineau's doctrine of race. In a long and meritorious historical introduction, Dr. Scheidt, a German anthropologist, gives the French count, who began to preach his doctrine of race in the middle of last century, a foremost place among the students of mankind. Put briefly, this doctrine implies that a nation's destiny depends entirely on its racial composition.

It is interesting to note what the French anthropologist has to teach concerning these matters, for Dr. Deniker, although born in Astrakan, was in all respects a Frenchman. Dr. Deniker was bred in the school of Topinard; some forty years ago he was known to anatomists by contributions made to the embryology and anatomy of anthropoid apes. Then he took to the study of human races, and published in 1900 the first edition of the work noted here [a review of the first edition appeared in our pages, April 28th, 1900, p. 1030]. On the eve of the great war he had made preparations for a second edition, but died just as the war ended, and so it has come about that this work, although issued in 1926, is in reality a production of pre-war times. Nevertheless, it is a valuable record of fact and opinion, compiled by one of the foremost anthropologists of Europe. Nowhere in his pages does the name of Gobineau appear; indeed, we are quite convinced that if the matter had been put to him, Dr. Deniker would have rejected the doctrine so forcibly promulgated by Count Gobineau.

It was, in fact, Deniker more than anyone who gave rise to the conception that all the nationalities of Europe are mongrel entities. He believed that war, commerce, and repeated migrations had utterly confused the racial issues of Europe. Certainly a survey of historical records leads to such a conclusion; but there is much to be said against Deniker's doctrine of racial confusion, only it would take us too far afield to discuss such a large problem now. It is more to the point to note the criteria on which Dr. Deniker relied to separate the racial types of Europe from each other. They were three in number—stature, shape of head, and colouring. All of these characters are variable even within human stocks which we have reason to believe have been isolated and uncontaminated for many generations. The degree of variability among the individuals of a true race or breed of mankind is much greater than is usually believed. We have only to attempt to apply Dr. Deniker's criteria to the population of any part of the British Isles to realize the chaos which follows such an attempt. Dr. Deniker's scheme of classification, however well it looks on paper, breaks down the moment we attempt to put it into practice in the field. So far as his account of human races is concerned, I think that the one given by Mr. A. H. Keane in *Man Past and Present* (a new edition of which was prepared by Mr. Quiggan and Professor Haddon, and issued in 1920) is superior in every respect. Dr. Deniker, however, included a survey of man's structure and culture as well as of his racial distribution, and thus his book covers a much wider field than does Mr. Keane's treatise.

In the middle part of last century—when Count Gobineau's first book appeared—anthropologists discriminated unhesitatingly Saxon from Celt by their respective mental, moral, and emotional characters. Everyone is familiar with the detailed critical lists then drawn up; indeed, they are still the stock-in-trade of politicians. Dr. Deniker dismisses such modes of racial discrimination as "banalities." Indeed, he cites only one exception to his general condemnation, and that is contained in the report of the expedition which Professor Haddon led to the Torres Straits. Tradition and education do materially affect the actions and reactions of man's mind, but no one who takes into account all the evidence of everyday experience can do otherwise than come to the conclusion that human races differ profoundly in mental outfit. Our difficulties lie in discovering reliable and effective methods of measuring mental differences; our present methods have hardly a rule-of-thumb value. Even Dr. Scheidt, who estimates Gobineau's doctrine of race so highly, is in agreement with Dr. Deniker as to the futility of our present methods of measuring the mind of a race.

Dr. Deniker, like Dr. Scheidt, believes that a race retains its physical characters however much its environment may be changed. Amongst other examples he cites the case of German settlers in Siberia and in Brazil; at the end of four generations these settlers are still German in their physical characteristics. He holds that any race—the fair Nordics, for example—can be acclimatized in *time* to arctic or to tropical conditions; this is one of the few passages in which Dr. Deniker touches on a practical problem. He admitted that South Europeans will become fitted for life in the tropics in a smaller number of generations than will be the case with natives of North Europe. Acclimatization, Dr. Deniker held, can be brought about only in one way—through the operation of Darwin's law of "natural" selection; the mortality, he conceived, would be heavy in the earlier pioneer generations, but ultimately, after an undefined number of generations, there should emerge descendants of the original race well adapted for a full and healthy life under tropical conditions. It is possible that amongst the Queenslanders of to-day there may emerge certain families who find that they can tolerate a tropical temperature better than their neighbours, and by means of such selected families the white fringe may gradually creep northwards into the tropics. Even Dr. Deniker, I think, would never have suggested that the experiment of acclimatization should be tried by plunging a European community in the midst of tropical surroundings.

Dr. Scheidt as well as Dr. Deniker has much to say concerning the offspring which results when one primary human race is crossed with another. Both authors agree that a hybrid child is in reality a mosaic of characters rather than a real blend. There is no doubt that Mendel's laws can be applied to many of man's inherited characters, but it is also clear that our knowledge concerning the modes of human inheritance is still in its infancy. Dr. Deniker hardly touches on the laws of heredity, whereas Dr. Scheidt, as is now usual in German treatises on anthropology, deals with them at great length. We see, too, that biometrical methods are receiving very full treatment in the anthropological systems of Germany. In short, the tendency to-day is to base anthropology on the methods of experimental biology rather than on the principles of human anatomy. Nevertheless, a full knowledge of the human body is the ultimate foundation of anthropology.

VITAL STATISTICS FOR ENGLAND AND WALES, 1926.

WE are indebted to the Registrar-General for the following statement regarding the birth rates and death rates and the rates of infantile mortality in England and Wales and certain parts of the country during 1926. The statement is issued for the information of medical officers of health. The birth rate and infantile mortality rate for London have been provisionally corrected for transfers.

ENGLAND AND WALES.

Birth Rate, Death Rate, and Infantile Mortality during the Year 1926 (Provisional Figures).

	Birth Rate per 1,000 Total Population.	Death Rate per 1,000 Population (Crude Rate).	Deaths under One Year per 1,000 Births.
England and Wales	17.8	11.6	70
105 county boroughs and great towns, including London	18.2	11.6	73
158 smaller towns (populations from 20,000 to 50,000 in 1921)	17.6	10.6	67
London	17 1	11.6	64

The death rate for England and Wales relates to the whole population, but that for London and the two groups of towns to the civil population only.

England and Wales.

The birth rate is 0 5 per 1,000 below that of 1925, and, with the exception of the rate in 1918, the last year of the war, is the lowest recorded.

The death rate is 0.6 per 1,000 below that recorded in the previous year and is equal to that of 1923, the lowest recorded rate.

The infantile mortality rate is 5 per 1,000 births below that of 1925, but 1 per 1,000 above that of 1923, the lowest on record.

British Medical Journal.

SATURDAY, JANUARY 22ND, 1927.

HIGH BLOOD PRESSURE.

PHYSIOLOGY has long been, and is now more than ever, recognized as the basis of scientific physic; forty years ago the late James Andrew, senior physician to St. Bartholomew's Hospital, often recommended his clinical clerks to take Michael Foster's *Physiology* as their textbook, thus, though it is in no way really analogous, momentarily recalling Sydenham's advice to Sir Richard Blackmore to read *Don Quixote*. Since then the study of disordered function has displaced the pursuit of a structural basis for the manifestations of disease. Within the last three years two Harveian Orators have respectively insisted on "The debt of science to medicine" (Sir Archibald Garrod in 1924) and on "The debt of medicine to the experimental method of Harvey" (Sir John Rose Bradford in 1926)—two sides of a shield, but both showing the inseparable ties of physiology and medicine. During and since the war physiologists have been busy in helping to apply physiology to the prevention and elucidation of disease. Among physiologists who have thus brought physiology into more intimate touch with medicine is Professor J. A. MacWilliam of Aberdeen, who has long been actively engaged on the problems of blood pressure, and practising medical men owe much to him for popularizing the auscultatory method of estimating it; this was before the war, and in collaboration with his pupils Melvin and Murray. Since then he has written a series of papers, among which special reference may be made to a comprehensive one in *Physiological Reviews* (1925, v, 303-335), and to the last of several that have appeared in these columns. It is on "High blood pressure from the physiological aspect," and was given as a lecture before the James Mackenzie Institute for Clinical Research at St. Andrews. It is printed in the opening pages of our present issue.

In this paper Professor MacWilliam brings forward many interesting and suggestive points which deserve attention. Thus, as evidence of the importance of combining the auscultatory and tactile methods in estimating the blood pressure, he points out a fallacy resulting from repeated or continued compression by the armlet—namely, that the systolic pressure may appear to be lower by the auscultatory method than by the tactile procedure. A review of the numerous mass statistics now available of blood pressure at different ages shows that clinical observers have overestimated the normal rise in blood pressure in the second half of life, and that it does not amount to more than 15 mm. Hg. It is remarkable that cerebral haemorrhage, the incidence of which in persons with high blood pressure is estimated to be about 20 per cent., often occurs during sleep, when the systolic pressure normally falls. Light is thrown on this paradox by the observation that, whereas in sound sleep the blood pressure falls, in disturbed sleep the systolic pressure may rise by 50 to 70 mm., and the diastolic by 30 mm. Hg. Recollecting what occurs in the waking hours as the result of emotion, this effect of excitement during sleep is not surprising.

The view that high blood pressure is a compensatory process is criticized, and shown not to be supported by the argument that lowering of the blood pressure may make the patient worse. Further, some quite recent observations of Dr. C. Reid are quoted against the hypothesis that a heightened blood pressure necessarily improves renal efficiency as regards the excretion of nitrogenous waste products. While it is possible that there are two categories of supernormal blood pressure—one with, the other without a raised capillary pressure—there is no certainty that the pressure in one set of capillaries is an index of the general capillary blood pressure in a way analogous to arterial blood pressure.

The possible causes of high blood pressure are discussed at some length, and, although the matter is still left open for final decision, the pressor influence of supernormal blood pressure would appear to be exerted primarily on the central nervous system rather than directly on the peripheral vessels as a whole. Impaired blood supply to the vasomotor centre in the medulla is admitted as a cause, but the difficulties in ascribing this to an arterio-sclerotic condition of the blood vessels supplying the medullary vasomotor centre are set out. The existence of pressor substances, such as renin and guanidine, on the one hand, and of a deficiency of depressor substances on the other hand, is impartially discussed. Reference is also made to the observation of Drs. Orr and Innes that large quantities of water by the mouth reduce high blood pressure, and, further, keep it down for comparatively long periods. This method of treatment, which, of course, has been practised empirically at spas, is thought to act by washing out metabolites presumably of protein origin. This fall of blood pressure was observed both in normal and hyperpiesic persons, and it will be interesting to hear the results of the further investigations which Professor MacWilliam promises, for it is obviously of much practical importance to know in what kind of case the method is likely to be successful. On *a priori* grounds patients with impaired renal excretion would appear to be unsuitable, and Drs. Orr and Innes find that when the diuresis cannot keep pace with the intake of water, as may occur in renal inefficiency, there is a rise of blood pressure above the original level before the fall appears. But if this were the only contraindication, the washing-out treatment should be much more effective than it has been in the past in persons with pure hyperpiesia—that is to say, without any renal change or disorder.

THE SECOND VALUATIONS OF APPROVED SOCIETIES.

THE results of the valuations of approved societies are of great interest and importance, not only to the societies themselves, but to the medical profession also, as well as to all who are concerned with making the most of all available resources to improve the health of the nation. These results have not at the present time any direct bearing upon the question of the remuneration of insurance practitioners, for the cost of medical benefit (which, of course, includes a number of items in addition to this remuneration) is now, up to the limit of 13s. per insured person, a first charge on the insurance fund; but they determine the sum which, during the five years following the valuation, will be available for the provision of "additional benefits," which may, and usually do, include several "treatment benefits" as well as increased cash payments to sick insured persons. The first valuations were made as at December 31st, 1918. The second valuations have been, for convenience and

economy, effected in two groups, as at December 31st, 1922 and 1923, respectively. The report of the Government Actuary on these second valuations has just been issued, and a summary will be found in this week's SUPPLEMENT (p. 27).

The result of the first valuations was a surprise; the result of the second valuations would have been even more surprising if intelligent anticipation had not in large measure forestalled it. With a very small proportion of almost negligible exceptions, it is true, as Sir Kingsley Wood declared not long ago, that "approved societies are extraordinarily prosperous bodies, piling up huge surpluses which are, of course, partially built up by State contributions." The first valuations disclosed an aggregate surplus of £17,192,968, of which £9,184,087 was certified by the valuers to be disposable in the provision of additional benefits. The second valuations show total surpluses exceeding £42,000,000, and of this £27,000,000 is available for distribution as additional benefits in the ensuing quinquennium, the remainder being carried forward. These disposable surpluses must not be confused with the total of the accumulated funds of societies, which are represented by much larger figures. The purpose of the carrying forward of these relatively large amounts from the surplus to the next valuation is to provide for the possible contingency of the next ensuing quinquennium being markedly less prosperous than that over which the valuation extends. In that disappointing eventuality the carried-over amount would be available to assist in maintaining the then existing additional benefits over a further period. Even assuming that the great war has been the cause of a considerable part of the prosperity of approved societies, and recognizing that the rate of interest earned by capital over the past few years is not likely to be maintained at the same level, the contingency referred to must be regarded as remote and the provision made for it generous. To quote Sir Kingsley Wood again: "In all probability the amount of the surpluses, especially on the third valuation, will remain undiminished." As the Government Actuary's report itself says: "The general result of the valuation is to disclose a very strong financial position. . . . The level of the surpluses brought out on the present occasion is markedly higher than that disclosed in 1918."

Prominent among the factors, in addition to those mentioned above, which have resulted in such an advantageous situation has been the favourable sickness experience between the two valuations. This has been especially favourable as regards men, but, though there has been a continuous increase in the claims of women, particularly in the case of prolonged illness, these claims still remain below the expectation. There can be no doubt that the work of the medical profession—not merely the skill and attention given by insurance practitioners, but the efforts made by other branches of the profession to improve health conditions and increase the vitality of the industrial population—has been one of the most important contributory causes of this satisfactory state of affairs. The reduction in the birth rate, too, has, of course, resulted in a lessening of the amount required for maternity benefit. The year 1926 is outside the period over which the second valuations have extended, and it is well known that during the greater part of that year the sickness claims of insured persons directly affected by the coal stoppage were largely increased. The causes of this abnormal increase are the subject of anxious consideration by the Insurance Acts Committee, as well as by the Ministry of Health and approved societies. It is to be hoped that conditions such as these will not recur, for the effect on a financial position less strong than that now shown to exist might be serious, and must in any case be important; but it must be remembered that the second valuation period has itself included a time of prolonged industrial depression, which had an inevitable effect on contribution income.

Of the total number of insured persons 97 per cent. (some fourteen and three-quarter millions in all) are entitled to participate in the additional benefits to the provision of which this large sum of £27,000,000 is allotted. The benefits themselves, however, whether treatment or cash, will be very unevenly distributed. Each society or branch is separately valued, and is an entity for these purposes, and the sums at their disposal per member are unequal. Their schemes for the character of the additional benefits to be made available are also diverse, some preferring cash benefit to treatment benefits, and some providing one kind of treatment benefit rather than another. It is possible that the sums allotted to certain treatment benefits by certain societies may in the event prove not to be correctly proportioned, and it is to be hoped that some adjustment may be allowed, if necessary, in this matter; but the total sum available should be adequate for its purposes, and it does not appear from the report that there is any financial reason why the extension of the insurance scheme in the direction of a specialist, consultant, and laboratory service, as recommended by the Royal Commission, should meet with any undue delay. The situation does show, however, with its large surplus on the one hand and its unequal and unsatisfactory division on the other, that when viewed from the standpoint of the prevention and cure of sickness the approved society system is very imperfect, and may even be regarded as an obstruction to the full use of these large sums of money in the interest of public national health. As the Minority Report of the Royal Commission puts it, if an approved society "is composed of extremely healthy members it can, by providing a wide range of additional benefits, many of a medical character, enable them to become still more healthy. If, on the other hand, it is composed of members whose standard of health is below the average, or who may be engaged in hazardous occupations or occupations which call for a higher degree of physical strength than others, the current expenditure on cash benefits leaves no margin for surplus, and as a consequence that section of the community who need all possible services of a preventive and curative character are limited strictly to the bare statutory benefits of the Act."

SIR BERKELEY MOYNIHAN.

MANY beyond the ambit of the city and its University, and not influenced by the individual sentiment of loyalty a great medical school inspires, will be interested in the announcement made in a letter published elsewhere in this issue (p. 163) to the effect that a fund has been opened in Leeds to get Sir Berkeley Moynihan's portrait painted. That will be at any rate its primary object, and in the circumstances the most interesting and appropriate. His is a great name in surgery, and the record of his achievements will remain, but it will not wholly explain to future generations the position he has attained in the profession to-day; for this some understanding of a remarkable personality is necessary, and nothing will better help to convey it than a good portrait. Subscriptions, which must not exceed £5, are to be sent to the Treasurer, Moynihan Portrait Fund, Town Hall, Leeds.

DIET AND CANCER.

To the irresponsible amateur it may seem easy to ascertain the causal relationship between tomatoes or meat-eating and cancer or appendicitis; he may think it as obvious as that between Tenterden Steeple and the Goodwin Sands or the influence exerted by the cat population on the fertility of red clover. But the scientific worker knows how many and dangerous are the pitfalls which beset such an inquiry, and how much watchful patience and hard work are needed to come at any trustworthy result. The report to the Ministry of Health on diet and cancer[1] by Drs. Monckton Copeman and Major Greenwood, just published, offers a case in point. As Sir George Newman remarks in his prefatory note, although of late years knowledge has increased of the effect of dietaries on nutrition in general as well as in specific morbid conditions, we have no evidence supporting a direct connexion between dietary and cancer, even cancer of the gastro-intestinal system. Therefore it seems to us that it was certainly worth while to enlist the willing help of Cardinal Bourne and other leading authorities of the Roman Catholic organization in an inquiry into the deaths from cancer in religious communities, whose members live under strict dietary rules, which vary in different communities, but involve in all more or less complete abstinence from meat and from rich and abundant food; all of these practices have been accused of contributing to the production of cancer. Such considerations no doubt moved the Departmental Committee on Cancer to undertake this investigation. The conclusion is that previous statements as to monastic communities cannot be substantiated, and that the incidence of fatal cancer in all such religious orders as were investigated is not lower than that in the general population at like ages; this applies to females as well as to males. The authors of the report testify gratefully to the value of the help of Cardinal Bourne and that of Monsignor Jackman and others who undertook what they justly describe as a most laborious business. While Drs. Copeman and Greenwood state that the labour has not all been in vain, they evidently entertain a certain sense of grievance that they should be expected to devote their energies for long periods to the investigation of "assertions supported merely by the vague pseudo-statistical evidence which is customarily cited respecting the roles of certain articles of common consumption in the genesis of cancer." To the main body of the report are appended some interesting notes on the incidence of fatal cancer upon inmates of prisons and mental hospitals. In the former case the inmates resemble those of religious houses only in the circumstance that they receive a diet less varied and less rich in proteins and fats of animal origin than the general population. An investigation of Goring's data leads to a negative conclusion, but the authors suggest that a further investigation may be desirable, and express a hope that they may be able to undertake it. As regards the mental hospitals, the factors involved are so many and the circumstances so different from outside life that no inference can safely be drawn from such statistics as exist.

MEDICINE IN ANCIENT GREECE.

ONE of the periodical social evenings of the Royal Society of Medicine was held on January 17th, when the guests were received by Sir James Berry, the President of the society, and Lady Berry. In the library there was disposed an interesting collection, lent by the Wellcome Historical Medical Museum, bearing on medicine and surgery in ancient Greece, and this was the subject of an illustrated talk by Professor A. W. Sheen of Cardiff. The lecturer began with Aesculapius, who, he said, was probably a real person, subsequently made into a god. His sons, Podalirus and Machaon, were also famous for their skill in medicine, though they were warriors as well, and Machaon was wounded, which was a matter of great concern to the Greeks, for, said one of them, "A physician is worth a host of other men." After mentioning some of many references to medicine in Homer, Professor Sheen spoke of the health temples—a remarkable development of Greek medicine—and gave an account of the famous temple at Epidaurus, with its open-air wards and facilities for the entertainment as well as the treatment of patients. The cult of the serpent, which was sacred to Aesculapius, was practised in the healing of various conditions, including blindness, as witness Aristophanes:

> Then the god clucked
> And out there issued from the holy shrine
> Two great enormous serpents . . .
> And underneath the scarlet cloth they crept,
> And licked his eyelids as it seemed to him.

The pinnacle of Greek medicine was reached during the latter half of the fifth century B.C., in the time of Hippocrates. The medical school of Hippocrates was established on the little island of Cos—all that was greatest in ancient Greece appeared to have come from her islanders—where there was worked out a startlingly rational system of treatment of disease. Professor Sheen took his audience through a few extracts from the works of Hippocrates to show the character and genius of this remarkable man, or perhaps of his school, for some of the work suggested the existence of a clinical unit quite of the modern type. One quotation had a very modern note: "This I know moreover, that to the human body it makes a great difference whether bread be fine or coarse." There were very detailed statements in the writings of Hippocrates concerning operation arrangements. Professor Sheen quoted some passages which seemed to suggest that Hippocrates anticipated stethoscopic methods, and proved how rational he was with regard to epilepsy, which at that time was looked upon as a "sacred disease." Hippocrates regarded it as in no wise more sacred than any other, but as having a natural cause from which it originated like other affections. The vote of thanks to Professor Sheen was proposed by Dr. Cawadias, who mentioned that he had lived in Epidaurus during the greater part of his childhood and youth, and, indeed, that his father had been instrumental in discovering the famous health temple. He reminded the audience that one of Sir William Osler's favourite quotations, taken from the work of Sir Henry Maine, was to the effect that, apart from the blind forces of nature, everything that moved us to-day was of Greek origin. The vote of thanks was seconded by Lady Berry, and heartily carried.

AMALGAMATION OF RADIOLOGICAL SOCIETIES.

AT a special general meeting of the Röntgen Society on January 11th it was agreed, with one dissentient, to amalgamate the society with the British Institute of Radiology. The proposer of the effective resolution, Dr. G. W. C. Kaye, said that negotiations between the two bodies had been proceeding for two years. The title of the new organization would be, "The British Institute of Radiology incorporated with the Röntgen Society." There would be no alteration in the character of the work and objects of the society in consequence of the amalgamation. All the present members would be accepted without entrance fee as members of the new body on an expression of their willingness to adhere to the new memorandum and articles of association. A new class of members was proposed in the shape of associates, as it was felt that there was a considerable body of medical men, not sufficiently interested in the subject to seek full membership, but desirous of some connexion with such an organization.

The annual subscription for full members would be raised from its present rate of two guineas to three guineas. In return for the increase the members would have the advantage of the library and other facilities at the Institute's premises in Welbeck Street, as well as an enlarged and improved journal. Provision had been made to ensure the continuance of the Silvanus Thompson Memorial Lecture of the society and the Röntgen award. Dr. A. E. Barclay, in seconding the resolution, said that he hoped the character of the Röntgen Society, whose membership had always included physicists and makers of apparatus as well as medical men, would be fully reproduced in the new body. As an earnest of this the new and enlarged council was to be, as the Röntgen Society's council always had been, half medical and half lay. The chief discussion at the special meeting centred round a provision in the proposed articles whereby the council of the united body may at any time submit for approval to the members a system of classification of members according to qualifications or other distinctions, the members in a particular class to be allowed to use after their names an abbreviated title. This was interpreted by some of the lay radiographers who have been members of the society for many years as likely to result in de-grading to their disadvantage, and their spokesman asked for an explicit assurance that all members would continue in the new body on an equal footing, and that in fairness to the long-established lay radiographers, through whom very largely x rays were introduced to the medical profession, their status would be safeguarded. Dr. Kaye declared that there was no immediate intention to act upon this provision. It was inserted, as things were often inserted in articles of association, so that in some, perhaps remote, eventuality a certain course might be taken without the necessity of altering the articles. As the scheme stood at present lay radiographers, like other members, automatically entered into the membership of the new body. Dr. N. S. Finzi, the president of the society, spoke to the same effect. A motion was, however, persisted in, that with a view to allaying the apprehensions of some members who were well established lay radiographers, the meeting should declare its intention of protecting the professional interests of such members should they be jeopardized by the amalgamation. This was lost by a large majority, but Dr. Finzi from the chair pointed out that it had not been negatived on its merits, but simply on the ground that it was unnecessary in view of the assurances which had been given. The resolution for amalgamation is to be brought forward for confirmation at a further meeting of the society on January 25th.

ANTHRAX AT THE ZOO.

ALTHOUGH the most important single source of loss among captive wild animals is tuberculosis—as Dr. H. H. Scott, the pathologist to the London Zoological Society, showed in a paper recently reported in this JOURNAL[1]—occasionally more spectacular outbreaks are encountered which are of direct medical interest. Thus, for example, in the Edinburgh Zoological Gardens some years ago there were several fatal cases of glanders among the great cats (glanders in carnivores is usually a very acute disease, although chronic in the normal host, the horse), which was traced to an infected horse which had been used for food. In the last few days of last year two of the elephants in the London Zoological Gardens died suddenly from anthrax. This disease is not uncommon in domestic animals in this country, especially in Scotland; and it is very common in Asia, where, in addition to destroying large numbers of domesticated mammals, it is a veritable scourge to elephants—in Burma alone it is estimated that over 5,000 die yearly from this cause. Fortunately the disease has not been previously encountered in the London Gardens, although menageries in other parts of the country have been attacked. Thus, for example, in 1911 Mr. Somers, a veterinary surgeon, reported an outbreak in which four great cats, two polar bears, five other mammals, and a vulture died from acute anthrax, while several other animals showed symptoms of the disease, but recovered.[2] The attack in the recent outbreak in the elephants was very acute, and the animals died within forty-eight hours. The origin of the infection is unknown, but some of the foodstuffs are suspected. Apart from its scientific interest, the outbreak has a definite public health significance, as four of the men who came in contact with the carcasses contracted the disease. Thanks, however, to the very prompt diagnosis of anthrax in the animals by Dr. Scott—he had diagnosed it within an hour of the necropsy—immediate and energetic steps were taken by the authorities of the Zoological Society to prevent the infection spreading and to detect any already affected. All in-contacts were examined, and these four cases were detected at an extremely early stage—long before the malignant pustule had developed its typical form. They were removed to St. Thomas's Hospital, and, under serum treatment, are, we understand, progressing favourably. The premises at the Zoological Gardens have been disinfected, and all steps have been taken to prevent any possibility of risk to the public visiting the gardens. The authorities at the Zoological Gardens are to be congratulated on the prompt steps they took to diagnose and search for anthrax in the animals and in-contacts, and for the energetic measures which they and the Government departments interested in the outbreak put in force to prevent the subsequent spread of the disease. The incident, too, serves to indicate some of the possible dangers from wild animals, and to commend the wise policy of prompt necropsy of all animals which the London authorities have adopted.

[1] BRITISH MEDICAL JOURNAL, December 4th, 1926, p. 1053.

THE PREVENTION OF HEART DISEASE.

DR. J. A. NIXON of Bristol has had the opportunity, along with Dr. Phillips, medical superintendent of the Southmead Hospital, of watching the effects of prolonged rest in bed upon several children suffering from rheumatic fever and chorea with early carditis, and has reported the results in a recent number of the *Bristol Medico-Chirurgical Journal*. Dr. Nixon observes that every writer since Francis Sibson, whose article in Reynolds's *System of Medicine* was published in 1877, has advocated rest for the rheumatic heart. Sibson found that cases of rheumatic fever were less often attacked by carditis when kept rigidly at rest, and this the Bristol observers say may be accepted as proved beyond a shadow of doubt. The question to which they particularly direct the attention is as to what happens to patients treated by a rigid system of rest whose hearts are already affected. Although Dr. Nixon has formed the impression that patients so treated escape with less serious damage to the heart, he says that the observations at Southmead did not encourage the hope that a sound heart will result from prolonged rest in bed, even when the child has been in hospital before the very earliest sign of cardiac involvement was observed. In deciding whether a child should still be kept in bed the general and local cardiac conditions must be considered. The general conditions include cessation of pyrexia, abatement of joint pains and choreic movement, and relief of cyanosis or dyspnoea. The local conditions comprise the rate and rhythm of the heart, the position of the apex beat, the size of cardiac dullness and the size of the heart as estimated by x-ray examination, the disappearance of bruit, and the

[2] *Veterinary Record*, February 25th, 1911.

clearing up of pericardial signs. In spite of the most careful attention to these points he concludes that the physician has little or no control over the result. "One begins to wonder," he says, "whether rheumatic fever, like syphilis and encephalitis lethargica, is a disease which throws out no recognizable signal of arrest, and has no known criterion of cure. We must all have seen the length of time during which choreic movements may persist in Sydenham's chorea without pyrexia or cardiac lesion. Presently an acute pyrexial exacerbation occurs and the heart becomes affected. The disease in such a case would, no doubt, have been regarded as cured if the movements caused by a chance involvement of the corpus striatum had not continued." Dr. Nixon, therefore, raises the question whether a new attack of rheumatic fever is merely a relapse in the course of a single infection. The experience at the Southmead Hospital of trying to stem the progress of rheumatic carditis by a rigid system of rest, such as that advocated by Sir Archibald Garrod, does not inspire confidence in the opinion that by such measures heart disease in adults can be prevented. Dr. Nixon is inclined to associate himself with the warning uttered by Dr. J. A. Glover, during the discussion on rheumatic infection in children, at the Annual Meeting of the British Medical Association in Bath, to the effect that it is rheumatic fever we must study to prevent, and that we really know very little about the etiology of the disease. Rheumatic fever can be, and habitually is, prevented, Dr. Nixon observes, from attacking the children of a certain social grade, seeing that rheumatic fever is practically non-existent in our great public schools. In his view it is probable that nutrition rather than environment is the main factor in preventing attacks and recurrences.

VOCATIONAL GUIDANCE.

THE National Institute of Industrial Psychology[1] was formed some two years ago to provide a scientific association for studying the human factors which enter into industry and commerce, and for applying the results in practice. On behalf of commercial firms it conducts investigations into the effects of movement, rest, lighting, humidity, ventilation, seating, methods of payment, and so forth, and particularly into the value of systematic selection and training of workers. It is an attempt to apply the methods of psychology to everyday work. An experiment is being conducted in the London area by the Institute in collaboration with the London County Council and the Ministry of Labour, aided by a grant from the Carnegie United Kingdom Trust. During the past two years 600 children leaving elementary schools at the age of 14 years have been given vocational advice based on mental and physical tests. The children are followed up so that there may be gathered some judgement of the value of the method in the light of the success of those advised. The tests applied to the children are twofold. There is a general examination based upon the findings of the school teachers which appraises general intelligence, attainment in school subjects, practical ability, and deftness. The special examination by the psychologists estimates ability for clerical work, mechanism, dressmaking, engineering, packing, memory for form and design, attention and concentration. The results are discussed at a conference between the two sets of workers, and their separate recommendations show a very high proportion of general agreement. Proof of the value of these findings and recommendations must be sought for in the after-history of the children. The follow-up is as yet in its early stages, but so far as they go the figures are encouraging. Information has been obtained in 161 cases. Of these 103 are in work of the same or similar kind to that recommended, and 58 in different work. In the former group there are no children who have expressed dissatisfaction, and only 4 have changed their posts more than twice; in the latter group 18 are dissatisfied, and 10 have had from three to eight different jobs in less than a year. If a friendly hint is not out of place, we would suggest that the Institute, or the editor of its future reports, might well study the psychology of its readers in the arrangements of the printing. The paper and type are excellent, but the lines of print extend right across the page, and are eight inches long. Such a length is most uncomfortable and wearing, and by no means conducive to study.

RECENT ADVANCES IN THE TREATMENT OF ANAL FISTULA.

IT is said that more reputations are lost over the treatment of anal fistula than in any other department of surgery. It is certainly true that in few conditions is it so difficult accurately to determine the extent of the disease or to forecast the probable duration and extent of the treatment that may be required, for unsuspected pockets and innocent-looking but tortuous side-tracks may render what promises to be a successful operation a complete and exasperating failure. At a meeting of the Subsection of Proctology of the Royal Society of Medicine held on January 12th two new methods were described which would appear to hold out considerable promise of minimizing the chance of unsuccessful operations, and of shortening the prolonged and tedious period of convalescence. Mr. E. C. Norbury and Mr. C. N. Morgan described a means of determining the exact topography of a fistula by the injection of lipiodol followed by stereoscopic x-ray photographs. As is well known, lipiodol has already proved its worth in the radiography of spinal tumours and of such diseases of the lungs as bronchiectasis, and owing to the density of its x-ray shadow the narrowest fistulous track, with all its unsuspected branchings, is clearly revealed. The technique is quite simple, and the pictures obtained permit a fairly accurate estimate of the extent of operative intervention necessary, and the probable duration of the after-treatment, to be arrived at. At the same meeting Mr. W. B. Gabriel brought forward the suggestion that the after-treatment of fistulae might be materially shortened by the simple expedient of using Thiersch grafts for the granulating wound. Photographs of various stages of a case treated by this method were shown, and it was evident that a considerable amount of time had been saved. If further experience confirms the value of these two procedures, all surgeons will have reason to be grateful to Mr. Norbury and Mr. Gabriel for introducing easy methods of simplifying and shortening the treatment of a tedious and troublesome condition.

CENTENARY OF UNIVERSITY COLLEGE, LONDON.

IN order to obtain further financial assistance for the extension of its buildings, the veteran Sir Philip Magnus on April 27th last delivered an interesting address on the birth of University College, London, one hundred years ago, which has now been printed by the University of London Press (price 1s.). It contains many historical details about the origin of University College, or, as it was first called, London University. Although universities were established in or before the twelfth century in Salerno, Bologna, Padua, and Paris, and although Sir Thomas Gresham in 1548 endowed seven professorships with the intention that there should be a university in London, it is remarkable that no effective steps were taken until 1825, when Thomas Campbell the poet and Isaac

Lyon Goldsmid the banker, who were friends, and often met as members of the Literary Club, advocated the establishment "of a great London University" which should be liberal in the sense of being free to all, irrespective of religious belief; for at that time Roman Catholics, Nonconformists, and Jews were excluded from Oxford and Cambridge. Campbell and Goldsmid lost no time in interviewing Mr. (later Lord) Brougham, and Campbell's famous letter, occupying nearly two columns in the *Times*, appeared on February 12th, 1825. Two years later, on April 30th, 1827, the foundation stone of the present building was laid by H.R.H. the Duke of Sussex. When the first working session was nearing its close, and there were more than 550 students, steps were taken to apply for a charter which, *inter alia*, would have empowered the new University to grant degrees. This proposition met with considerable opposition, due to the strong feeling, bordering on contempt, held by many, especially those with orthodox religious views, for "the Gower Street institution." Eventually a compromise was arrived at, and two charters were granted by King William IV—one creating a new and distinct body, to be called the University of London, with power to confer degrees; and the other incorporating the previously existing London University as University College, London, the students of which would be eligible, together with those of other duly recognized teaching bodies, to obtain degrees on passing examinations at the newly constituted University of London. Sir Philip Magnus gives a sketch of the difference between "a College" and "a University," and recalls the circumstances which led up to the passing of the Act of 1871 abolishing all religious tests for admission to the universities.

INFLUENZA.

THE epidemic now under way has begun to influence the mortality rates, although not very seriously. In the great towns of England and Wales the deaths certified as due to influenza, which had amounted to 69 and 86 in the two previous weeks, increased to 172 in the week ending January 8th. The increase in that week was relatively very much greater in London, for which the figures are 16, 17, and 72. The notifications of pneumonia tell the same story—an increase from 1,173 and 1,514 to 2,033 in England and Wales, and from 174 and 193 to 345 in London. In the extra-metropolitan districts the largest proportional increase in pneumonia was in the south-east, but the populous north-western and Yorkshire areas also showed substantial increments. In London the total mortality assigned to pneumonia, bronchitis, and other diseases of the respiratory organs, and to influenza, in the three weeks ending January 8th, was almost the same as twelve months ago—1,159 against 1,135. Some further increase is to be expected. In fact, in the week ending January 15th the deaths from influenza in London increased to 137, and those in the great towns to 326; while London notifications of pneumonia reached 370, and those in England and Wales numbered 1,869. But the present visitation seems to be of a mild type, and bids fair to be less formidable than that of 1922, or even than the milder recrudescence of 1924. We shall not, however, seek to enter the fellowship of the prophets. Indeed, those of the fellowship who do forecast epidemics confine themselves to dates of occurrence, and offer no opinions as to duration or severity. The *Times*, we notice, is still a staunch supporter of Dr. Brownlee's thirty-three weeks' cycle, but we are surprised that none of the newspaper paragraphists have come upon Mr. Spear's simpler, and on the whole more successful, rule, which is described and illustrated in the annual report of the London County Council for 1925 (Volume iii, pp. 34-37). Mr. Spear's rule for predicting the date of the next maximum is as follows. Subtract the serial number of the week in which a maximum of influenza mortality occurs from 34½, then double the remainder will be the number of weeks to the next maximum. For instance, in 1921 the week of maximum influenza in London was the thirteenth. Subtracting from 34½ we have 21½. Hence we should expect the next maximum in forty-three weeks. Actually the next maximum occurred forty-one weeks later, in the second week of 1922. In thirty-three years Mr. Spear's rule gave a result correct within four weeks twenty times, while Dr. Brownlee's method only scored eight "inners." Mr. Spear remarked that "there are several instances in which the hypothesis fails, but with the reservation which thus attaches to any particular forecast it may be noted that a prevalence of influenza is indicated about the end of 1926." This has been verified, and his rule, which would give a maximum of mortality about the third week of the year (in London), is not likely to be far wrong. This balancing of epidemics about the thirty-fifth week of the year has been noticed in the data for Copenhagen as well as in London experience; the rationale of it is difficult to grasp. Mr. Spear's method stands on a quite different basis from Dr. Brownlee's. Dr. Brownlee reached his interval by a periodogram analysis of several years' data, and the result is an average result; he did not take each successive epidemic as a new starting-point. It must also be said that Mr. Spear's criticism of Dr. Brownlee's process, quoted in the London County Council report (p. 36) ignores Dr. Brownlee's quite cogent rejoinder (see the Ministry of Health's *Report on the Pandemic of Influenza, 1918-19*, p. 576). Dr. Brownlee's object, illustrated in several of his other researches, was a much more philosophical one than any sporting attempt to "spot winners." He has always looked at the secular problem of an epidemic disease as a whole, seeking a general description of its evolution and evidence of changes in the *tempo* of that evolution. Since for influenza the statistical record is short and exceedingly imperfect, it was not to be expected that a complete elucidation would be obtained. Dr. Brownlee's attempt remains, however, as a good example of the method that must, when data are sufficient, lead us to important discoveries. For merely "spotting winners" we should give preference to Mr. Spear's plan, although, were betting on dates as common as in the eighteenth century, we should not expect to make more than a moderate competence by its use.

INTERNATIONAL CITATION.

WE have recently received from Professor Léon Bernard, writing from the Institut d'Hygiène of the University of Paris, a letter in which, after thanking us for the terms in which his book on pulmonary tuberculosis was noticed in these columns, he protests against one sentence in our review. Having said that though Professor Bernard was essentially a product of the French school, he yet did not carry "his ideas to the degree of exclusivism that is so annoying in some of his compatriots," the review continued: "It is true that he has been rebuked by the Americans for neglecting to take notice of their work." But we pointed out that in his preface he said that he had not set out to write a treatise, but rather to record his own opinions, founded on the investigations of himself and of his pupils. The essential passage in Professor Bernard's letter may be translated as follows: "I desire to challenge the general criticism made against French authors that they neglect the opinion of foreign writers. If you will compare the large French treatises with similar works published by English, American, or German writers you will not fail to agree with me that this criticism is unjust, and that French authors cite foreign writers much more often than they are themselves quoted by their colleagues in other countries." We are very glad to publish this disclaimer on Professor Bernard's authority.

Union of South Africa.

[FROM OUR CORRESPONDENT IN CAPETOWN.]

MEDICAL FACULTY OF CAPETOWN UNIVERSITY.

THE medical faculty of the University of Capetown has greatly increased its activities in recent years, and the following account of the conditions under which medical degrees are granted by the University will be read with interest.

Three degrees are granted—namely, Bachelor of Medicine and Bachelor of Surgery (M.B., Ch.B.), Master of Surgery (Ch.M.), and Doctor of Medicine (M.D.). The University also grants a post-graduate diploma in public health (D.P.H.).

The entrance examination for the degree of M.B., Ch.B. is the matriculation examination, conducted until 1917 by the University of the Cape of Good Hope, and now by the Joint Matriculation Board. Students may enter at the commencement of the first term (March), which is the method advised, or at the commencement of the third term (July). Registration as a medical student is obligatory. The curriculum occupies six years from the date of registration as a matriculated student; alternatively, the degree of B.A., embracing certain qualifying courses, may be taken, and thereafter the final four years of the curriculum for the degree of M.B., Ch.B. Medical students attend the Somerset Hospital, where clinical instruction is given by the honorary medical staff. A fee of ten guineas entitles a student to a perpetual ticket to the hospital. No candidate can be admitted to the degree of M.B., Ch.B. until he or she has attained the age of 21 years. University residences for both men and women students are provided. Students not living with their parents or guardians must satisfy the authorities that they are residing at houses approved by their parents or guardians.

Curriculum for the Degree of M.B., Ch.B.

The courses for the first professional examination and the minimum number of hours to be allotted to lectures and practical work in the several subjects are: botany special, 60 hours; zoology special, 80 hours; physics special, 120 hours; inorganic chemistry special, 150 hours; anatomy I, 200 hours. The courses in anatomy I, physics special, and inorganic chemistry special extend over four terms, those in botany special and zoology special over two terms.

The courses for the second professional examination are: organic chemistry special (extending over two terms), anatomy II, physiology and physiological chemistry I. The courses for the third professional examination are: bacteriology, pathology, and pharmacology; a course in psychology is also required. In the final professional examination the courses are: medicine, surgery, obstetrics, and gynaecology, public health, medical jurisprudence, and toxicology, and courses in the following special subjects: ophthalmology, psychological medicine, venereal diseases, skin diseases, diseases of the ear, nose, and throat, and diseases of children.

In the fourth year the courses for candidates who begin at the commencement of the academic year are: (*a*) in the first two terms, principles and practice of surgery, clinical surgery (surgical dressership), revision anatomy, obstetrics, anaesthetics; (*b*) in the second two terms, surgery, clinical surgery, obstetrics, practical and clinical obstetrics, anaesthetics, and medical jurisprudence and toxicology.

The courses for the fifth year are: (*a*) for the first two terms of the calendar year, principles and practice of medicine, clinical medicine, gynaecology, practical and clinical obstetrics, public health, and vaccination; (*b*) for the second two terms, principles and practice of medicine, clinical medicine, practical and clinical obstetrics, gynaecology, infectious diseases, psychological medicine, vaccination, and leprosy.

In the sixth year the courses are: clinical medicine and clinical surgery, operative surgery, [illegible]ical obstetrics (not fewer than [illegible]ases of the ear, nose, and throa[illegible] of children, venereal diseases, [illegible] in addition, optional courses in tropical medicine and radiology.

The final professional examination consists of two parts. Part I: (*a*) medical jurisprudence and toxicology, and (*b*) public health. These may be taken separately. Part II: (*a*) medicine, (*b*) surgery, (*c*) obstetrics and gynaecology, [illegible]sycho-logical medicine, venereal diseases, sk[illegible] the ear, nose, and throat, and diseases of [illegible] may not enter for the second part of the final professional examination unless he has completed the first part. Before being admitted to the degree of M.B., Ch.B. each candidate is required to subscribe to the following declaration: "I, A.B., solemnly declare that as a graduate in medicine of the University of Capetown, I will exercise my profession to the best of my knowledge and ability for the good of all persons whose health may be placed in my care, and for the public weal; that I will hold in due regard the honourable traditions and obligations of the medical profession, and will do nothing inconsistent therewith; and that I will be loyal to the University and endeavour to promote its welfare and maintain its reputation."

MEMORIAL TO THE LATE DR. S. B. SYFRET.

New wards for non-European patients, forming a memorial to the late Dr. Stephen B. Syfret, who was accidentally drowned while bathing at Hermanus in February, 1919, were opened at the Rondebosch and Mowbray Cottage Hospital on October 25th, 1926. The wards provide accommodation for six male and six female patients, and with bathrooms, etc., form a self-contained block connected with the main hospital building by a passage way. Running the whole length of the new block is a stoep wide enough to permit of beds being brought out. The cost of the new extension was £3,466; half of this amount was raised by public subscription, the other half being met by the Cape Hospital Board. In the passage way is a large photographic portrait of the late Dr. Syfret, and a mural tablet with the following inscription:

"Dedicated to the memory of Dr. Stephen Syfret, who in his lifetime was a member of the honorary medical staff of the Rondebosch and Mowbray Cottage Hospital. This building was erected by his many friends and the Cape Hospital Board as a memorial to his life and work, especially amongst the poor."

After this tablet had been unveiled by Mrs. S. B. Syfret, Mr. A. B. Reid, on behalf of the memorial committee, handed over the new block to the Cape Hospital Board, on whose behalf it was accepted by Mr. M. C. Vos, chairman. Mr. Reid referred in sympathetic terms to the noble work of Dr. Syfret, both as a doctor and as a man, work which had commanded from all sections of the community the highest respect and affection. Dr. Syfret, he said, had in a special sense been the friend of the poor, both white and coloured, and his death was an irreparable loss. After his untimely end it had been felt that his memory should be perpetuated by some practical token of their regard, and this addition to the hospital where he had laboured and had been loved was the outcome.

PORTRAIT OF THE LATE DR. A. REITH FRASER.

In recognition of the invaluable services rendered to the Cape (Western) Branch of the Medical Association of South Africa (British Medical Association) by the late honorary secretary, Dr. A. Reith Fraser, it was decided by the council of that body to procure a suitable likeness of Dr. Fraser to be hung in the rooms of the Association in Capetown. As the result of the efforts of a small sub-committee to which the work was entrusted, an excellent photographic enlargement of a portrait of Dr. Fraser was placed in position in time for the annual general meeting last November. In addition to the portrait, some seventeen originals of Dr. Fraser's pen-and-ink caricatures of his colleagues in the profession have been framed and hung in the vestibule of the Association's rooms The expense involved was met by small individual subscriptions on the part of members of the Branch.

PRESENTATION TO DR. G. W. ROBERTSON.

A pleasant little ceremony took place at the Government Bacteriological Laboratory in Capetown on November 23rd, 1926, when Dr. G. W. Robertson, on the eve of his retirement from the office of Government pathologist, was presented with a cheque. Dr. Hugh Smith, in making the presentation, explained that it was a token of the very high esteem in which Dr. Robertson was held by his colleagues all over the Union and in Rhodesia and the South-West Protectorate, a large number of whom had taken part in the movement. Had it not been for Dr. Robertson's express wish to make the ceremony as informal as possible, there would no doubt have been a large attendance. Dr. Hugh Smith concluded by speaking of the good relations that had always existed between Dr. Robertson and the members of the profession, and by giving him the best wishes of the subscribers for the future.

Dr. Robertson qualified in London in 1893, and came to South Africa four years later as assistant bacteriologist to the Health Institute, at that time established at Grahamstown. In 1901 he was transferred to Capetown, and since then had occupied the post which he now vacates. He retires on pension at his own request, although he has been asked repeatedly by his department to continue in office. His many friends will be glad to learn that he has not

severed his connexion completely, for his part-time services will be retained by the Government in the capacity of consulting pathologist to the vaccine station at Rosebank. The remainder of his time will be fully occupied in agricultural activities on his beautifully situated farm near Stellenbosch.

THE CAPE HOSPITAL BOARD.

The reconstituted Cape Hospital Board came into office on October 26th last. Its membership under the new Provincial Ordinance has been reduced from thirty-six to eighteen. The following persons constitute the new Board:

Hospital Representatives: The Rev. A. P. Bender, Messrs. W. D. Hare, A. E. Adams, E. Graham Green, and Mrs. Duncan Baxter.
Divisional Council Representatives: Mr. J. Michau, Chevalier Callanan, and Dr. C. J. Juritz.
City Council Representatives: Mr. W. James and Mrs. H. Horwood.
Wynberg, Durbanville, and Simonstown Municipalities: Mr. H. F. East.
Administrator's Nominees: Mr. M. C. Vos, Dr. P. M. Dancel, and Mr. C. H. Dickinson.
Joint Peninsula Institutions Representative: Dr. F. M. Morris.
Representatives of the Honorary Medical Staffs of the Cape Hospitals: Professor A. W. Falconer, Dr. Julius Petersen, and Mr. H. A. Moffat.

The last-named three were elected by ballot by the honorary visiting medical officers of the New Somerset Hospital, the Woodstock Hospital, Rondebosch and Mowbray Cottage Hospital, the Victoria Hospital (Wynberg), and the Peninsula Maternity Hospital.

India.

RABIES IN SOUTHERN INDIA.

THERE was a slight increase in the number of patients treated in the antirabic department of the Pasteur Institute of Southern India, at Coonoor, during the year ending February 28th, 1926; the total was 572, as compared with 489 in the previous year. Antirabic vaccine was also issued to local centres for 4,072 persons, as compared with 4,402 in the previous return. The percentage of reports of the progress of the patients treated has improved very much, and it is evident that greater care is now taken to detect cases of rabies. Registration of deaths from this cause has been in force in the Madras Presidency since 1913, and in 1922, 1923, and 1924 there was a pronounced increase, which was attributed to the interest aroused by the issue of antirabic vaccine to district headquarter hospitals. Statistics collected over many years at the Pasteur Institute show that, on an average, death occurs in one out of thirty-six persons bitten by rabid animals treated with antirabic vaccine, as compared with one out of sixteen not so treated. It appears from the figures available that between 1913 and 1924 at least 60,000 persons in the Madras Presidency were bitten by rabid animals, but only about 10,000 of them received antirabic treatment. Eight scientific papers dealing with research work of various kinds done in the Institute were published during the year in the *Indian Journal of Medical Research*.

OUT-PATIENT LEPER CLINICS IN BURMA.

In response to an appeal by the Burma Branch of the British Empire Leprosy Association, subcommittees have been formed in nearly every headquarters town throughout the province, and over 57,000 rupees have been collected. In his report on the public health administration of the province, Lieut.-Colonel E. Bisset, I.M.S., director of public health, describes how a public meeting in connexion with the appeal led to a greatly increased attendance for out-patient treatment at the St. John's Leper Asylum, which is three miles out of Mandalay, and Dr. Peacock, the medical officer of the asylum, decided to open a small out-patient dispensary in the town for diagnosis and early treatment. At this dispensary forty-four patients were treated between May 1st, 1925, and March 31st, 1926; eight of them were too far advanced for dispensary treatment and were advised to enter the asylum. As the result of the first year's work Dr. Peacock concludes that out-patient leper clinics, if cautiously conducted, would be very popular in Burma, being within easy reach of the people and distinct from existing asylums, so that there would be no danger of loss of employment resulting from treatment. He thinks that such dispensaries would make it possible to get into touch in course of time with the entire leper population, which could not happen if treatment was limited to resident leper institutions. Such clinics would not be expensive to maintain, and would serve as centres for the supply of information about leprosy to those infected as well as to the healthy members of the public. It was reasonable to hope that patients would come for treatment in the earlier and more curable stages of the disease. Dr. Peacock adds that the clinic has brought to light the frequency of leprosy among Europeans and Anglo-Indians.

PROGRESS OF VACCINATION IN INDIA.

Reports on vaccination work during the last three years in the Central Provinces, the Presidency of Madras, and the Province of Assam indicate that, although there has been some increase in the number of vaccinations, yet the proportion of the vaccinated population is still so low as to call for greater efforts along educational and administrative lines. Revaccination in particular is neglected, and in some districts the indifference of the vaccinators is held to be largely to blame. While vaccination is compulsory in some towns, many rural areas escape, although the opposition is less marked among villagers. In Bihar and Buldana local schoolmasters have been trained as vaccinators with very good results, and it is suggested that this procedure might well be more general. Major T. D. Murison, I.M.S., director of public health in Assam, strongly urges that each municipality should be provided with a well equipped small-pox hospital, and that the disease should be made notifiable in rural areas where it is prevalent. In Madras, where the health department was reorganized in 1923, there has been a considerable increase in the number of health inspectors and first and second class vaccinators; the probationary class is gradually disappearing. Major A. J. H. Russell, I.M.S., director of public health, refers to the urgent need for compulsory vaccination throughout the presidency, and of fuller powers being given to the district and municipal health officers. The registration of vital statistics is still imperfect, but in spite of these drawbacks very considerable progress has been made during the three years in vaccination in Madras, so that the hope is entertained that small-pox will gradually be brought under control. There is still need for more prompt notification of outbreaks, since many deaths occur before preventive measures can be taken. Lanoline lymph has now been replaced by glycerin lymph, and successful vaccinations have reached the high figure of nearly 95 per cent. The small-pox mortality in Madras steadily declined during the three years. In his annual report on vaccination in the Punjab for the year 1925-26, Lieut.-Colonel W. H. C. Forster, I.M.S., director of public health, reports a great increase of vaccination in the province during the last three years. He states that vaccination is the only protection the general population has against the disease, since small-pox hospitals do not exist, except in Simla, and systematic segregation and disinfection are not attempted. He hopes that still further progress will follow when each district has been supplied with a medical officer of health. The education of public opinion by systematic propaganda has proved extremely valuable, but he is pessimistic about the possibility of opening the eyes of municipalities to their responsibility in this connexion.

MADRAS GENERAL HOSPITAL.

At the Madras Government General Hospital 67,689 out-patients and 9,916 in-patients were treated during 1925; there was an increase of non-European patients and a decrease of Europeans as compared with the previous year; surgical operations numbered 2,974, or 504 more than in 1924. Clinical instruction was given to 251 students. In his report of the work of the hospital during 1925 Lieut.-Colonel M. N. Chaudhuri, I.M.S., gives a full statistical account of the administrative side, while the three surgeons

and the three physicians supply clinical details, including brief notes of the more interesting cases. Comment is made on the rarity of Pott's fracture among Indians, only 10 cases having been admitted during the three years 1923-25, as compared with 119 cases of fracture of both bones of the leg and 101 cases of fracture of the femur treated in this period. The X-Ray Institute is being enlarged, and a considerable amount of new apparatus, including a deep x-ray therapy outfit, a "radiostat" high-tension transformer, tungsten arc and mercury vapour lamps, and a new diathermy apparatus, has already been installed; three whirlpool baths will be added shortly.

University of Bombay.

The *Bombay University Calendar* for the two years 1925-26 and 1926-27 indicates the steady progress that is being made in the spread of educational facilities in this part of India. A list is given of the twenty-six colleges now affiliated to the University—namely, Elphinstone College, Bombay; Deccan College, Poona; Wilson College, Bombay; St. Xavier's College, Bombay; Gujarat College, Ahmedabad; Rajaram College, Kolhapur; Baroda College, Baroda; Fergusson College, Poona; Samaldas College, Bhavnagar; Dayaram Jethmal Sind College, Karachi; Bahauddin College, Junagadh; New Poona College, Poona; Karnatak College, Dharwar; Maganlal Thakordas Balmukunddas Arts College, Surat; Willingdon College, Sangli; Sind National College, Hyderabad; Hansraj Pragji Thackersey Arts College, Nasik; Sydenham College of Commerce and Economics, Bombay; Secondary Training College, Bombay; Poona Agricultural College, Poona; College of Engineering, Poona; Nadirshaw Edulji Dinshaw Civil Engineering College, Karachi; Government Law College, Bombay; Indian Society's Law College, Poona; Grant Medical College, Bombay; and Seth Gordhandas Sunderdas Medical College, Bombay. At the convocation for conferring degrees on August 18th, 1926, the Chancellor, the Right Hon. Sir Leslie Wilson, G.C.I.E., presided, and the Vice-Chancellor, Sir Chimanlal H. Setalvad, K.C.I.E., delivered an address which is printed in full in the *Calendar*. He emphasized the importance of concentrating the colleges and hostels in a university quarter. The provision of university extension work among adults was also desirable, and a college of technology was required to include mechanical and electric engineering, textile industries, and applied chemistry.

Ireland.

Clean Milk.

In the third of a series of articles specially contributed to the *Irish Independent*, Professor J. W. Bigger, M.D., of Trinity College, Dublin, described pasteurization as a process in which milk was heated to a temperature sufficient to kill the greater number of bacteria present. The correct method was to heat the milk to 145° F. for half an hour, and then to cool it rapidly. Almost all the bacteria capable of causing diseases, including tuberculosis and typhoid fever, were killed, but it did not render safe a dirty and badly contaminated milk. It also killed the bacteria which caused milk to sour, and so a pasteurized milk kept sweet longer than if untreated. The objections to pasteurization were that it interfered with the digestibility of milk, and it destroyed, either partially or completely, the vitamins so essential for growing children. If pasteurized milk was used the vitamins lacking in it must be replaced by the addition of other foods containing them, such as cod-liver oil and fresh fruit. Pasteurization was improper if used, as too often it was, to render saleable a milk which had deteriorated, to mask careless methods, or as a substitute for the cleanliness which ought always to be exercised in the collection of milk. The hygienist could not countenance pasteurization by a dealer who purchased milk from farmers at a distance, who made no investigation of the conditions under which the milk he pasteurized was produced, and who paid the same price for clean as for dirty milk. Milk should be protected from contamination from the farm to the consumer's house, and the most satisfactory method of achieving this was to supply it in bottles filled and sealed at the farm. Properly carried out, bottling was excellent, but if badly done it was dangerous. No one should be permitted to bottle milk unless he had proper plant for the thorough cleansing and sterilization of his bottles; to put milk into unsterile bottles was criminal folly. Legislation was necessary for grading milk, since at present the terms "Certified" and "Grade A" were unprotected and meaningless. A good judgement of the quality of milk was given by noting the length of time it kept sweet. Good milk would remain sweet for several days, and any milk which soured within twenty-four hours, without being kept at a warm temperature, was dirty. Milk must be protected against contamination in the home by being kept in the bottle until required or in a jug covered with a plate to keep out flies and dust. Every vessel used for milk should be washed, first with cold water, then with hot water and soda, and finally scalded with boiling water. Jugs used for milk should be plain, without crevices, inside or out, where dried milk, containing millions of bacteria, might lodge. Milk should always be kept in the coolest part in the house, and the bottle or jug be placed in a large basin filled with the coldest water available; this should be replaced by fresh water when it became warm. All these precautions were necessary, whether the milk was raw or pasteurized. If these conditions were fulfilled, and the milk became sour, it was certain that it had been contaminated by dirt. Those in Ireland who desired further information would find the Irish Clean Milk Society ready and anxious to supply it.

Ulster Medical Society.

A meeting of the Ulster Medical Society was held in the Medical Institute, Belfast, on January 13th; in the absence of the president, Dr. Nolan, the chair was taken by Dr. Loughridge (Whitewell). After routine business, the chairman proposed the following resolution, which was seconded by Dr. O'Flaherty (Belfast), and carried with acclamation:

> The Ulster Medical Society desires to place on record the pleasure and appreciation of its Fellows and members that the honour of Knighthood has been conferred by His Majesty the King upon Dr. Thomas Houston, a past-President of the society, in recognition of his invaluable services to scientific medicine. The council unanimously recommends that the name of Sir Thomas Houston be added to the list of honorary Fellows of the society.

The meeting was purely a clinical one, and a number of interesting cases were shown by Dr. F. M. Allen, Professor Fullerton, Mr. H. P. Hall, Mr. S. T. Irwin, Dr. R. Marshall, Dr. Ivan McCaw, Mr. R. J. McConnell, and Mr. G. R. B. Purce. Dr. Marshall's exhibit of eight cases of congenital lues of varying types included one resembling pernicious anaemia, one with spastic paraplegia and mental deficiency, one resembling osteo-arthritis, and one with classical teeth and enuresis, all improved by arsenic treatment. The exhibitors demonstrated their several cases with the aid of charts, x-ray photographs, and typed histories.

Scotland.

Vital Statistics for Glasgow in 1926.

A HEALTH bulletin issued by the Glasgow Public Health Department shows that the number of deaths recorded during the past year in the city was 15,626, as compared with 15,332 in 1925, representing a death rate of 14.2 as against 14.0 per 1,000 for the previous year. The death rate from tuberculosis of the lungs was the lowest yet recorded, being 0.85 per 1,000 of the population, while the rate for 1925 had been 0.92. With regard to other forms of tuberculosis, the number of deaths had been 320 for 1926 as against 395 for 1925, death rates respectively of 0.29 and 0.32 per 1,000. It would thus appear that non-pulmonary tuberculosis is tending to be less severe in type, probably in consequence of the improvements in

facilities for treatment made during recent years. The infant mortality rate for the year was 103 per 1,000 births, as compared with 102 in 1925 and 119 in 1924. The year 1926 showed the third lowest infant mortality rate yet recorded, despite the fact that there had been a severe epidemic of measles. The births registered during the year were 24,394, giving a rate of 22.3, which was 0.9 lower than the rate for 1925.

EXTENSION OF PERTH INFIRMARY.

A new maternity block at Perth Royal Infirmary has been erected and equipped, at a cost of about £15,000, by Lord Forteviot, and was opened on January 11th. The new building is one of the first separate maternity institutions to be erected in connexion with a hospital in Scotland, and is a self-contained unit, situated to the north of the infirmary. The one-story building contains two large wards of eight beds each, with separate special side wards, two containing one bed each, and two with two beds, thus accommodating in all twenty-two patients. All the wards face south, the large ones being placed at either end of the building and having windows on three sides. Adjoining one of them is a large room for cots; additional accommodation includes a lecture room, linen room, waiting room, and an examination room. A pillared verandah, with a glass roof, extends nearly the whole length of the building, and the wards connected with it, by means of French casements opening to the floor. At the north side of the building is placed the theatre, lighted from the north by a window extending almost the whole length of the wall, and by a large roof light; adjoining rooms for sterilizing and the preparation of dressings are provided. The building is centrally heated by radiators; all the wards have open fire-places, and the ventilation is entirely modern. With the opening of this maternity unit Perth will become a training centre for qualification for the C.M.B. certificate.

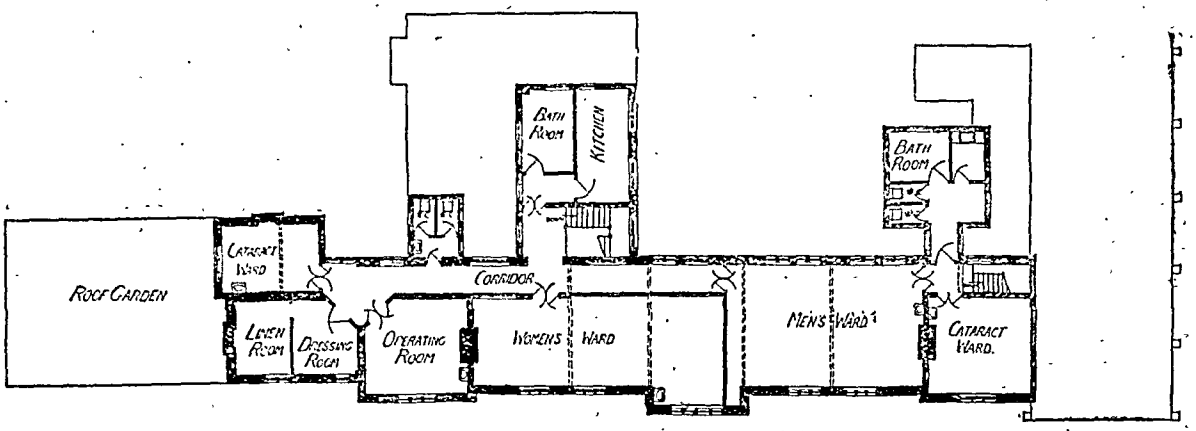
THE PROBLEM OF EVOLUTION.

The first of a course of ten weekly lectures on evolution was delivered by Professor J. Y. Simpson in the Department of Natural History at Edinburgh University on January 12th. The course is intended to be a continuation of a series of lectures on the philosophy of natural history started in 1886 by the late G. J. Romanes and continued by him for five years; later on they were resumed by Dr. A. D. Darbishire, lecturer in genetics, who unfortunately died in 1915. After a consideration of the meaning of the term "evolution," Professor Simpson gave an historical review of various ideas on evolution which had been advanced from the time of the early Greek philosophers to the close of the eighteenth century. All these ideas had offered only the alternatives of transformism and creationism, and as the former conception grew in exactness the influence of the latter waned. Examples were given of popular notions in regard to transformism, such as that of the transformation of the barnacle into the barnacle goose, as related in the work of Silvesten Giraldus Cambrensis (1187). The transformist's view of the sixteenth century was definitely stated by Sir Walter Raleigh in a passage occurring in his *History of the World* (1614). Leibnitz's law of contiguity and unity had created a favourable atmosphere for the teaching of transformism. The doctrine of descent with modification from previously existing forms was, Professor Simpson said, more surely founded now than ever before, but great uncertainty had recently developed as to the method of evolution and the factors involved in it. The problem was now seen to be much more complex than was originally supposed. The doctrine of descent was an induction from a large number of facts whose basis continually broadened and so became more secure.

TRAINING THE BLIND.

The annual social meeting of the Mission to the Outdoor Blind for Glasgow and the West of Scotland, held in St. Mungo Hall, Glasgow, was attended by some nine hundred persons with defective eyesight. Dr. A. S. McGregor, medical officer of health for the city, presided, and in the course of an address stated that negotiations were now in progress for the acquisition of a factory in the north-east part of the city, where it was hoped to provide facilities for training between two and three hundred young blind persons in various forms of manual work. He expressed the opinion that there was still room for a great deal of improvement in the conditions of work and life for blind people. Mr. W. R. Halliday, a member of the home teaching staff of this mission, recently received a notice that the President of the French Republic had, on the recommendation of the Department of Labour, Health, and Social Welfare of the French Republic, conferred upon him a gold medal in recognition of his services on behalf of the blind. The activities of Mr. Halliday have done much to awaken public interest in the methods adopted in other countries for dealing with the blind; and the mission in Glasgow and the West of Scotland has, through his efforts, been brought into close relation with other kindred organizations in France and Germany.

England and Wales.



WELSH NATIONAL MEDICAL SCHOOL.

THE special meeting of the court of the University of Wales was held in Shrewsbury, according to notice, on January 14th, but did not arrive at a decision with regard to the draft charter prepared by the court for the incorporation of the Welsh National School of Medicine as an independent school of the University. The attendance of members from South Wales was good, but that of members from North and Mid Wales was, it is reported, meagre. The adoption of the petition to the Privy Council embodying the terms of the new charter proposed by the University Court was moved by the Hon. W. N. Bruce and seconded by Alderman William George. The grounds for the dissent of University College, Cardiff, were developed by Principal Trow, who moved an amendment, seconded by Dr. Rocyn Jones, to refer the matter back to the council of the University. Principal Trow repeated the arguments against the establishment of the School of Medicine as a separate unit, and reinforced them by reading the answer of Mr. Alexander Grant, K.C., to certain questions submitted to him by the college. Mr. Grant held that in the draft charter the council of the University had exceeded its powers, and that it could not, under its present charter, or under the suggested altered charter, engage directly in teaching work or set up a school or schools under its direct control for the purpose of providing education in any subject; the proposal also, he considered, infringed the rights of the college under its charter. Mr. Grant concluded by advising that the matter was one for settlement, and that the college council should consider carefully any reasonable proposal that the University might put forward. A vote was taken by ballot, and the amendment carried by 53 votes against 48. It was understood that negotiations would be continued between the council of the University and the college, and it was subsequently decided that their result should be brought before the July meeting of the University Court.

AN OPHTHALMIC CLINIC.

The Coventry and Warwickshire Hospital.

Adjacent to the Coventry and Warwickshire Hospital is the Sir Thomas White School for Girls, a large building which during the war was used for the accommodation of wounded soldiers, and for the eye department, which was housed on the ground floor. During the period of financial depression which followed the war the whole block was closed, and for four years eye cases were treated in the general surgical wards. When the depression passed away the building was remodelled and a new lavatory block added. The ground floor was used for medical wards and for maternity work. The upper floor was rearranged and adapted for the eye department, and was opened for cases

The Coventry and Warwickshire Hospital: Ophthalmic Wards.

on March 1st, 1926. Sufficient time has now elapsed to show that it is well adapted for its purpose.

We are indebted to Mr. T. Harrison Butler, ophthalmic surgeon to the hospital, for the following description of the ophthalmic clinic, and for the block plan by which it is illustrated.

The operating theatre is floored with "parvino pavement," and the walls are enamelled dark green. Excellent illumination is given by a large side window with a south aspect. The operations are all performed early in the morning, so this aspect is satisfactory. A blind outside the window enables the theatre to be darkened for discission operations. The majority of the operations are carried out under a Rayner triple-beam lamp, which concentrates three beams upon the eye and avoids shadows. A Weiss point-o'-light projector is employed during discission. A Mellinger ring giant magnet is used for the extraction of steel fragments from the interior of the eye—a somewhat frequent operation at Coventry. Adjoining the theatre is a linen room and a dressing room for the staff. No one is admitted to the theatre who is not wearing special shoes.

The following table shows the number of patients treated during 1926.

Number of Patients treated during 1926.

Foreign bodies	3,429
New out-patient cases	1,667
Out-patient attendances	3,475
In-patients from March 1st to December 31st ...	288
Operations in theatre, March 1st to December 31st	231
Total attendances, including foreign bodies ...	6,904

There are four wards—including large male and female wards, and two small wards; these are used as occasion dictates as cataract wards or for private patients, who are admitted under two schedules of fees, which include the fee of the surgeon, which is seven or fourteen guineas according to the means of the patient. This arrangement has worked well. The wards, which are enamelled white, are lighted by a row of windows facing south. As far as possible those patients whose eyes are bandaged occupy the beds under the window, and no complaints have been made of discomfort from glare. At night the wards are illuminated by indirect light reflected from the white ceiling.

There are two beds in the male cataract ward, and nine beds and one cot in the large male ward. The large female ward contains eight beds and four cots. The small female ward has one bed and one cot. It opens by a French window on to a roof garden, where in suitable weather the children sleep and during the day have the advantage of sunshine. It is proposed later on to build a roof over this garden so that extra beds can be accommodated.

The out-patient department consists of an examination room opening out of the general waiting hall and a large dark-room about thirty feet long. This length allows the refractions to be done without the use of cycloplegics, which are used only for children and for difficult adult cases. It is furnished with a slit-lamp, a Lister daylight illumination perimeter, and suitable testing lenses and standard illumination test types.

The whole of the department, both in- and out-patient, is under the charge of one sister, who has her own nursing staff. This plan leads to co-ordination of the two departments and to greater efficiency.

DEVELOPMENTS AT STOCKPORT INFIRMARY.

A new orthopaedic department at Stockport Infirmary has been built and equipped at a cost of £9,000; it was opened on January 13th by Lady Sheffield, one of the governors. The new building, which was urgently required to relieve the crowded state of the out-patient department, and to deal more effectively with the large number of crippled and deformed patients, has been erected adjoining the nurses' home at the back of the out-patient department. It includes a large room for massage, and good accommodation for electrical treatment and ultra-violet light therapy. The department is fully equipped with up-to-date apparatus, and there is a gymnasium for Swedish remedial exercises. Additional bedrooms for the staff have been constructed on the upper story of the building, thus supplying a much-needed extension to the nurses' home. It was stated at the opening ceremony that since 1917 the number of cases treated at the infirmary had increased by 50 per cent. Lady Sheffield said that Cheshire had already opened a number of after-care clinics for children, and it was hoped to establish several more in parts of the county where it was not possible to provide after-care treatment in connexion with hospitals. The cost of the new department has been met by voluntary donations, for which an appeal was issued last June. A large percentage of the patients treated will be crippled and deformed children.

CENTRAL MIDWIVES BOARD.

The Central Midwives Board at its meeting on January 6th, when Sir Francis Champneys was in the chair, received with regret the resignation of Miss M. O. Haydon, and recorded its appreciation of her services. In response to a request from the guardians of Newcastle-on-Tyne the Board agreed to continue its approval of Dr. Haslam as lecturer until March 31st, 1928. The Board considered that this would give the guardians ample opportunity to make arrangements for the pupils of the Wingrove Hospital to attend courses of lectures elsewhere. In reply to a letter from the secretary of the Midwives Institute, the Board stated that the use of the approved form for keeping ante-natal notes was obligatory, but that the existing stock might be worked out subject to the approval of the local supervising authority. The Board declined to undertake to send to the council of the Midwives Institute directions or orders for local supervising authorities, but promised to forward any that in its judgement might be helpful. The Board agreed that the London County Council should have the right to send two representatives to any conference of representatives of local supervising authorities under the Midwives Act which the Board might convene.

Correspondence.

THE MENTAL DEFICIENCY BILL OF 1926.

SIR,—May I beg space for some comments on Dr. Tredgold's important letter in the JOURNAL of January 8th concerning the bill which was withdrawn, rather than abandoned, just before the end of the last session of Parliament?

1. With the greater part of this letter, which refers chiefly to the working of the Mental Deficiency Act of 1913, I wholly agree. I have, indeed, for several years been convinced that the words "from birth or from an early age," which limit the definition of all persons proposed to be dealt with under the Act, had, as a matter of fact, occasioned considerable difficulty in administration under the Act. I do not think that this difficulty should have been found insuperable by medical men in the matter of certification; but some revision of the definition seems to have been necessitated even from a legal point of view alone.

2. I agree, further, that some such alteration as is contained in Section I, Clause (2) of the proposed new bill should be made, especially if it should still be deemed desirable that the present hard and fast distinction between the "lunacy" and "mental deficiency" Acts should be preserved. But before considering this clause as it stands in the draft bill I wish to emphasize my accord with Dr. Tredgold when he says, in the second paragraph of his letter, that in his experience (which has been very wide) of the working of the Act of 1913 he had "never known, or heard of, a single instance in which a person has been dealt with under it who was not in need of supervision." The need of the Act is clearly of an opposite kind. I have no doubt that most adverse criticisms of it have been mainly inspired by imperfect knowledge of facts, and a kind of obsession by the vague phrase "the liberty of the subject."

3. In considering the chief proposed alteration in the bill for 1926, which runs thus: "Mental defectiveness means a condition of arrested or incomplete development of mind, whether innate or induced after birth by disease, injury, or other cause," some important questions arise. In his approval of this clause Dr. Tredgold seems to assume that the aim of a mental deficiency bill is mainly, or at least most prominently, to protect the several classes of persons described: to be, as it were, the "charter of the feeble-minded"; and thus would regard the interests of the community at large, such as concern, for instance, the harm done by many feeble-minded persons, as of somewhat secondary importance. And, further, he seems to imply that the present coexistence of one law for the "insane" and another for the mentally deficient must continue. Now the group contemplated in the new definition includes the subjects of arrested or incomplete development of mind, whether innate or induced after birth by disease, injury, or other cause. These words, however, imply a distinction under the appearance of a single group devised for practical purposes: the cases of those with arrested development are indicated apart from those affected by "other causes." Those affected by the other causes, mentioned and unmentioned, are such as suffer from mental disorder or decay arising after the mind has attained to that degree of development which would enable the individual to transact the ordinary affairs of life.

It is to be noted that the new defining clause introduces the consideration of distinct pathological causes in connexion with these two groups; and it appears to follow that a considerable number of the last named group would approach clinically and naturally much closer to the class of mental cases now dealt with under the Lunacy Acts than it does at present. This would probably increase the acknowledged element of difficulty in certification which it is now sought to diminish or remove; and the introduction of the words "or other cause" would form a fresh stumbling-block for critics.

The advisability of avoiding the more or less disputed nature of the various causative elements in the production of cases of mental defect of all kinds, including, of course, all cases needing care and control under both the existing "lunacy" and "mental deficiency" Acts (*for these are all marked by defect of mind*), was fully realized by most of those who dealt with these matters on the Royal Commission for the Care and Control of the Feeble-minded, which published its report in 1908, and led up at last to the production of a bill in Parliament in 1912. It appears to me still that, as in the existing Lunacy Act and in the Mental Deficiency Act of 1913, it is much more important and less liable to cause difficulty, to define the actual condition of those especially requiring control, than to bring under any legal definition the matter of the causes of such conditions. The first Mental Defect Bill of 1912 was withdrawn by the Government, partly because of parliamentary opposition on the ground of its alleged interference with "liberty." The recommendation of the Royal Commission that the jurisdiction over the whole matter of mentally affected persons should be dealt with by one comprehensive authority was, as far as I remember, omitted from the bill on account of considerable opposition by some lunacy authorities at the time. The second bill, of 1913, introduced as its first section the statutory definitions of the various classes to be dealt with, some of which have now led to the proposal of the bill that has recently been withdrawn.

It is chiefly because I have in mind a certain class of mental cases, several of which fall readily under the group which is characterized by Dr. Tredgold as the subject of arrested mental development, but others of which are not clearly classifiable, that I greatly question the substance of the proposed Clause (2) of the first section in the bill of 1926. I am not convinced by Dr. Tredgold that this clause would not apply to adults quite as much as, or more than, that of the Act of 1913. I note that he admits that it would apply to such young persons in whom mental defect has been brought about before the termination of adolescence. In fact, any such bill must apply to adults.

One class of cases I would specially note is that of some criminals, the early lives of whom are often difficult or impossible to trace, but appear closely similar to those whose early history can be traced. It seems clear from Section 5 (*b*) of the new Act that adults, including such persons as have been just mentioned, would be included under the newly proposed definition in Section 1, Clause (2), for it is stated in 5 (*b*), with regard to certain persons: "If the place in which he is being so detained under the order of the court is not a prison or such a place of detention as aforesaid he shall be removed therefrom to a prison, or, *if he is child or young person*, to a place of detention."

This point seems important when the wording of the new legal meaning of it is closely considered; and is of special importance when it is applied, as it must be, if accepted, to the certification of criminals charged with more or less serious crime. There has lately been a great tendency (especially in the United States), which may easily become dangerous, to regard an increasing number of criminals as mentally diseased—defective or insane—who, it is said, should be treated as diseased persons rather than punishable law-breakers; and I would urge that the new definition of "mental defectiveness" is at once too vague and too comprehensive to afford a practicable substitute for the old definition which qualifies "mental defect" as "existing from birth or early years." For this new definition introduces the question of the *cause* of mental defect, and adds to those specified the words "*or other cause.*" I think that all cases of mental deficiency or "unsound mind," or "insanity," from whatever cause or causes arising, should, for the benefit of the community at large, as well as of themselves, be dealt with by one legal authority, the nature of each case being decided, as at present, by experts after due examination and observation, and that the old interpretation in the glossary of the existing Lunacy Act—that "lunatics" means persons of unsound mind, or "idiots"—is sufficiently definite and comprehensive to indicate all the mentally affected persons who are now dealt with by legislation, or whom it is desirable so to deal with by any further measures of care or control.

Sound scientific research is revealing more and more

clearly the dependence of mental disorders generally on discoverable physical causes, and thus the practical knowledge of such disorders must increase. The definition, however, of persons whom it is necessary to care for or to control should be made as simple and as intelligible as possible for practical reasons. And I would venture to suggest something like the following as a workable definition for the particular group now generally recognized as cases of "mental deficiency," and specially dwelt on by Dr. Tredgold: "*Mental deficiency means incomplete development of mind, either existing from birth or observed subsequently before the attainment of complete adolescence.*"

I have not touched upon any part of the Act of 1913 other than that of which the bill of 1926 proposes amendment, but I desire to express a hope that a form of words in the stead of "moral imbecile" may be substituted some day for this very equivocal and inaccurate term. Perchance this term might suffer abolition in lieu of correction?—I am, etc.,

London, W.2, Jan. 14th. H. BRYAN DONKIN.

MOYNIHAN PORTRAIT FUND.

SIR,—The retirement of Sir Berkeley Moynihan, Bt., K.C.M.G., C.B., etc., President of the Royal College of Surgeons of England, from the active staff of the University and General Infirmary at Leeds, affords to the general public, to those who have benefited by his skill and knowledge, and to his colleagues in the University and the medical profession, an opportunity of showing their high appreciation of his conspicuous services, not only to surgery, but also to the city of Leeds.

It is suggested that public recognition should take the form primarily of a portrait of Sir Berkeley Moynihan, to be placed in the Board Room of the General Infirmary.

The Moynihan Portrait Fund Committee, representative of public life, having been formed, invites public support, and on its behalf we shall be glad to receive donations. Whilst the smallest subscription would be welcomed, it is suggested that no individual amount should exceed £5. Cheques should be drawn in favour of the Treasurer, Moynihan Portrait Fund, and sent to the Lord Mayor's Rooms, Town Hall, Leeds.—Yours, etc.,

For the Moynihan Portrait Fund Committee,

HUGH LUPTON, *Lord Mayor of Leeds*,
Chairman and Treasurer.
L. R. BRAITHWAITE,
Vice-Chairman.
J. B. BAILLIE,
J. KAY JAMIESON,
T. F. BRAIME,
Members.

Leeds, Jan. 14th.

SMALL-POX IN THE COUNTY OF DURHAM.

SIR,—At a recent conference of medical officers of health in the county of Durham the position in regard to small-pox in the county was discussed and certain resolutions were passed. It was decided that a copy of the report of the conference, including the resolutions, should be sent to medical officers of health, to the press, to the British Medical Association, and to the Society of Medical Officers of Health, urging their unanimous support of the resolution (No. 5) relative to vaccination.

This resolution reads as follows:

"That this conference urges upon the Ministry of Health the importance of amending the Vaccination Acts with the object of making vaccination more general and efficient, as vaccination affords the quickest, most scientific, and most economic means of preventing and arresting outbreaks of small-pox."

One must necessarily sympathize with members of the public health service in Durham, on whom the present long-continued prevalence of small-pox must necessarily have thrown a heavy burden in extra work, worry, and anxiety. As, however, an appeal is being made to the public health service and the medical profession generally to support the resolution, it is necessary and proper that the issue raised should be carefully considered.

Although the wording of the resolution has been drawn in general terms, its object is clear—namely, to press the Government to tighten up the vaccination laws so as to make infant vaccination again compulsory, in fact as well as in theory. At present, of course, vaccination is really only compulsory in name.

How far does the history of compulsory vaccination in relation to small-pox bear out the claims made on its behalf? Briefly the history is as follows: It was in 1853 that vaccination of infants was first made compulsory in this country. In 1867 another Vaccination Act was passed with the object of making compulsion effective. The appointment of vaccination officers was provided for, though not made compulsory. In 1871 the great pandemic of small-pox reached Britain, and in that and the following year it swept the country, causing heavy loss of life. A further Act was passed making the appointment of vaccination officers compulsory.

During the two following decades, 1873-92, a vigorous policy of compulsion was pursued, and with much success so far as the proportion of infants vaccinated was concerned. This period, indeed, marks the high-water mark of compulsory vaccination. For England and Wales the proportion of infants successfully vaccinated averaged 87.3 per cent. of the births. The proportion dying unvaccinated, etc., accounted for 9 per cent., whilst the residue "unaccounted for" was only 3.7 per cent. We are never likely to obtain a larger amount of vaccination than was the case during this period. Indeed, it is fairly certain we could never attain again to anything approaching it. But what was the sequel as regards small-pox? During this period, be it observed, vaccination alone was trusted to and was regarded as our chief line of defence, and those modern methods of controlling small-pox—notification, isolation, surveillance, and vaccination of contacts—which have since proved so effective, were still in their infancy. The Infectious Diseases (Notification) Act, for example, was not passed until 1889, though it is true that many towns had local Acts earlier than this year.

Under these circumstances vaccination proved quite incapable of preventing widespread and fatal epidemics. Let me quote just a few examples.

(1) Sheffield had a serious epidemic in 1887-88. The disease ran riot. There were 4,705 cases, of which 4,151, or 88 per cent., were in vaccinated persons. Dr. Barry, who reported on the outbreak for the Royal Commission, stated that "Sheffield had obeyed the vaccination laws better even than the average of large towns." At this time compulsory notification of disease was not in force in Sheffield.

(2) In 1892-93 Warrington had an epidemic which was officially reported on for the Royal Commission by Dr. Savill. There were 667 cases, of which 62 proved fatal. Now Warrington was such a well vaccinated town that Dr. Savill wrote: "It might perhaps at first sight be a matter of surprise that a comparatively well vaccinated town like Warrington should have been the scene of such a severe epidemic of small-pox. I estimated that nearly 99.2 per cent. of the inhabitants had been vaccinated once in their lives before the outbreak, . . ." It can hardly be contended that neglect of vaccination had anything to do with this outbreak.

(3) In 1897-98 Middlesbrough had a serious epidemic. There were 1,411 cases, and of these no less than 1,213, or 86 per cent., were in vaccinated persons. Moreover, 103 of these vaccinated cases proved fatal.

These examples could be multiplied indefinitely. The total number of deaths from small-pox during the two decades was 3,832. During the second half of the period, as modern measures came more and more into vogue, the disease rapidly receded, most of the deaths occurring during the first half.

In the face of experience such as this it must surely be obvious that vaccination, however efficacious it may be in protecting the individual, is quite unreliable if trusted to as a weapon for protecting the community.

In 1889, in consequence of the strength of the agitation against compulsory vaccination, the Royal Commission was appointed, and they presented their final report in 1896. As the result of their recommendations the Act of 1898 was passed, with its loophole for the "conscientious objector." The loophole was further enlarged by the Act of 1907.

The medical profession were all along opposed to the "conscience clause," believing that it would lead to a decrease in vaccination. The event has proved that they were right. Since the "conscience clause" was passed vast numbers of parents have taken advantage of it, and infant vaccination has steadily fallen till now less than 50 per cent. of infants born are vaccinated. To-day, as we have said, infant vaccination is really compulsory only in name.

But the sequel as regards small-pox has been most unexpected. So far as the old-fashioned fatal small-pox goes—the kind of small-pox that caused the disease to be so much dreaded, the kind of small-pox that the Government of this country had in mind when they first made vaccination compulsory—it has virtually disappeared. Deaths from small-pox have quite ceased to influence our national statistics. In Leicester, the most unvaccinated city in the country, where less than 9 per cent. of all births have been vaccinated during the past forty years, there has not been a single death from small-pox for twenty-one years. Other unvaccinated towns have had a similar experience. Modern methods of fighting the disease, which have taken the place of infant vaccination, have proved so successful that it is no exaggeration to say that in this country severe small-pox is now more amenable to control, and causes a smaller mortality, than any other serious infectious disease.

What sort of a case, then, can we possibly make out to justify a reversion to really compulsory vaccination, a measure which would inevitably arouse great opposition among large sections of the public, and which is also by no means free from objection on medical grounds, for vaccination, after all, constitutes a definite, if temporary, interference with health?

The one and only argument is that an ultra-mild, non-fatal strain of small-pox—so different in its effect upon health from "old-fashioned" small-pox that some have even questioned if it really is small-pox at all—has gained access to this country, and, largely on account of its very mildness, is proving more difficult to control than the "old-fashioned" severe strain. Nevertheless, most districts invaded, where energetic measures have been taken, have successfully stamped it out. A few districts, including the county of Durham, where doubtless there have been special difficulties, have hitherto been less successful.

This failure in the county of Durham was attributed at the conference to the inadequacy of the available hospital accommodation, to the failure of medical practitioners to recognize the nature of the disease, and to neglect and indifference on the part of the public owing to the mild character of the disease. Possibly at the outset there were other causes.

Sir George Newman, in his report for 1925, speaking of small-pox, refers to a certain district in the North of England in which

> "all the ordinary measures necessary to limit the spread of the disease were neglected for a prolonged period, with the result that the infection overflowed and became widespread in surrounding districts. There is reason to believe that spread of the malady took place from that ill-administered district into at least eight other districts in the vicinity, and that the prevalence of small-pox which occurred on Tyneside was in no small measure due to the long-continued neglect in the district in question."

It is quite certain that any attempt to tighten up the Vaccination Acts would meet with strong and bitter opposition from a large section of the community. Incidentally, it will do nothing to increase the popularity of the medical profession. Of much greater importance is increased hostility to vaccination, which will almost inevitably ensue, making it more difficult to secure "emergency" vaccination when we really need it.

In view of the arguments set forth above, I would appeal to medical officers of health and the medical profession in general to consider carefully whether the proposal to press the Government to amend the Vaccination Acts in the direction indicated is really necessary or even desirable.—I am, etc.,

Health Offices, Leicester, Jan. 11th. C. KILLICK MILLARD.

*** A report on the small-pox situation in Sheffield and in the county of Durham will be found at page 147.

SURGERY IN GENERAL PRACTICE.

SIR,—I entirely agree with the remarks of "An Occasional Surgeon" in your issue of January 1st, p. 42. I am on the staff of a small hospital, and have for some years done practically all the surgery in a large general practice.

In reply to the eminent surgeons who criticize the general practitioner, I would make the following points: An eminent surgeon operates on a patient. In many cases he never sees that patient's wound again. The report of a house-surgeon, sister, or nurse, however capable, is a poor substitute for personal observation. When I operate on a patient I visit him several times a day for the first few days, and do all the dressings myself. I should say that I have a very clear conception of my own limitations; there are some operations which I should not attempt.

The following sidelight on the patient's view of the "eminent specialist" may be of interest. A few years ago I operated on a little boy for hernia. The grandparents are very wealthy people to whom expense is of little account. Recently the grandmother got an attack of subacute appendicitis. Thinking that possibly they would prefer someone more important than myself to perform the operation I wired to a London surgeon, warning him that I might want him. When I mentioned this to the patient's husband he was most indignant. He said that I had operated on the little boy with every satisfaction, and that if any operation was to be done I was to do it.

Incidentally I may say that the London surgeon, on receipt of my wire, sent two telephone messages—the first to the effect that his fee for coming would be 100 guineas (the distance is about 130 miles by rail), and the second to make it quite clear that this fee would not include the operation (if any).—I am, etc.,

January 1st. ANOTHER G.P. SURGEON.

THE PUBLIC, THE DOCTOR, AND THE MASSEUSE.

SIR,—Dr. Murray Levick's letter (December 11th, 1926, p. 1142) raises a point of the greatest practical importance. Phototherapy is now being given indiscriminately by a large number of nurses, masseuses, "institutes," and so on, and it is time that the dangers of this practice should be brought before the public and the medical profession by those who are qualified to do so.

It is unfortunate that lecturers and writers of books on actino-therapy lay such stress on its complete safety. Those who have had practical experience of this treatment know that different patients react in different ways and degrees to ultra-violet light, and that, to obtain good results, these differing reactions should be observed after each treatment and the subsequent exposure regulated accordingly. When the treatment is given to a healthy person merely as a "tonic" this exact supervision may not always be necessary, but the case is very different when such conditions as tuberculosis, asthma, and skin diseases are being dealt with.

Dosage cannot always be regulated according to the degree of skin erythema alone, but the constitutional symptoms must also be considered; and in such cases accurate observations and deductions can only be made by those who have been trained in clinical medicine. The choice of lamp, the dosage, the question of combining local with general treatment, and so on, are all matters which should not be left to unqualified persons to decide.

Dr. Kerr Russell, in his letter (December 18th, 1926, p. 1196), has pointed out the rashness of installing lamps in the home, and with this opinion I can only express the most emphatic agreement.—I am, etc.,

London, W.1, Jan. 4th. HUBERT M. ODDY.

MATERNAL MORTALITY.

SIR,—After forty years of general practice and a considerable amount of obstetrics during that time, one must have formed some views on the practice of that art.

I contend that we of the medical fraternity are going through a very unfair interference and criticism as to our work, by those who are riding hard for a whole-time service. We hear the specialist put in the forefront, the

midwife extolled for carrying out the dictums laid down by a certain section, and the medical practitioner is put forward only as a cleaner-up of any mess someone else creates, and takes the blame thereof.

I consider that in midwifery the general practitioner is the specialist, from his constant practice, and that this position should be recognized. We hear the doctrine of masterly inactivity extolled without any reference to the feelings, health, strength, and circumstances of life of the patient; they are only a cipher to be bandied about, for so many hours, in useless and feeble efforts at natural delivery, notwithstanding that with the strenuous lives we are living, and the bad food we have still to eat, and the heavy taxation and small means, the majority of patients are far from normal at the best of times.

The great sin of medical men seems to be the too frequent use of instruments. I would rather say it is the frequent want of a better acquaintance with those instruments, which is the fault of the schools in which they have been taught; properly used they have no danger.

It is the much advocated waiting, causing the foetal parts to lie for hours pressing on maternal parts with no hope of shifting, which causes soddening of the tissues, allowing germs an easy entrance at those points, and thereby causing sepsis. Again, who would dare to perform the simplest operation on a patient prepared as an obstetric case is prepared (in the majority of cases it would be suicidal), and yet the powers that be talk of germs being introduced by making a vaginal examination. There is no risk in examinations if the hands are surgically prepared each time; I strongly object to gloves in obstetrics because of the impossibility of their being sterilized over and over again.

Recent instruction as to reporting cases with a temperature of 100° F. sustained for three days is going to do infinite harm. First, it will alarm the patient; secondly, the many trivial causes for such elevation of temperature, well known to the general practitioner, make it quite unnecessary; and thirdly, it will utterly demoralize the nerve of young practitioners, who very soon would become quite unable to sustain the anxiety of conducting any case.

I have read Dr. J. S. Fairbairn's address (January 8th, p. 47) with great interest, but do not agree with the trend of his argument when he links medical men, midwives, and specialists together with hospitals as the solution. I would suggest: hygiene of the home; beds in the local hospital for special cases, attended by general practitioners, who should be left alone, away from the continual vexatious instructions of those who are working for whole-time service; better teaching in hospital as to the handling of those helps we have for the alleviation of suffering—forceps, turning, and artificial dilatation such as with de Ribes's bag, and judging the proper time to interfere when the natural efforts are from many causes futile.

I consider the Queen Victoria's Jubilee Institute to be one of the best of institutions, and the nurses are excellent; but I also think, with their limited experience, far too much is expected of them, and I certainly condemn the suggestion that drugs should be placed in their hands. We practitioners are put through a very severe test before drugs are placed in our hands; why should nurses with comparatively no training be allowed to use them? Even we are now forced to account for what we use—another vexatious restriction on our position as registered medical men. Also, I think sedatives are only another excuse for delay in obstetrics, because the medical man has not the courage of his opinion against the fads of to-day, which will be pushed on one side for other fads in due course. Of course, there are times in obstetrics when morphine is good, but they are the exception, not the rule.

In conclusion, I would like to suggest that a partial solution would be:

1. A coming down to earth with our ideas—cutting our coat to the amount of cloth we can afford.
2. Hygiene of the home.
3. Surgical preparation on all sides for an operation of much importance.
4. A general idea for all, with freedom of action.
5. A closer study of those helps which we possess by students while they are students.
6. A little less of statistics and more of the practical experience of the forever slighted general practitioner.

Finally, I would suggest that the medical practitioner should be allowed to have a voice in carrying out his practice, without the incessant interference of those who live on statistics, and use them in preference to practical experience. Of course, I am only speaking of practice, not research.—I am, etc.,

Wallington, Surrey, Jan. 13th. A. Z. C. CRESSY.

HEREDITARY MUSIC.

SIR,—In view of your notice of Dr. Louis Vezoux's *L'Hérédité Musicale* (January 8th, p. 70) your readers may be interested in Dr. Mjoen's investigation into the inheritance of musical talent. He examined the 442 children of 114 marriages, classifying musical talent in three grades—superior, musical, and poor.

When both parents were superior 72 per cent. of the children also were, the remaining 28 per cent. being musical; none were poor. When both parents were poor 90 per cent. of the children were also, 10 per cent. were musical, and none were superior. When both were musical 39 per cent. of the children were superior, 49 per cent. musical, and 12 per cent. poor. The marriages of superior with poor yielded 26 per cent. superior, 37 per cent. musical, and 37 per cent. poor.

These results certainly point to musical talent depending on Mendelian factors, though not of the simplest kind, and partially recessive to normal. Dr. Mjoen emphasizes that, whilst the qualities of the parents are usually a good clue to the qualities of the children, they are not infallible. The qualities of the stock, as judged by the collaterals of the parents, determine the abilities of the children. He quotes one particularly interesting case of a concert player, herself the mother by a musical husband of seven highly gifted children. But he was for long puzzled to account for her own talent, since her father, mother, and seven brothers and sisters had no musical gifts, until he found that she was the illegitimate child of a great musician belonging to a family of artists.—I am, etc.,

London, S.W.1, Jan. 11th. ELDON MOORE.

ERYTHROEDEMA AND ACRODYNIA.

SIR,—In the discussion following Sir Humphry Rolleston's presidential address at the Medical Society of London, on "Changes in the clinical aspects of disease" (BRITISH MEDICAL JOURNAL, January 15th, p. 100), the disease *erythroedema*, to which I alluded, has been mistakenly printed *erythroderma*. I may add that the former name, first applied in 1914 to an apparently new disease in children by Dr. H. Swift of Adelaide, in Australia, had the disadvantage of wrongly suggesting that true oedema was one of its obvious symptoms. This is not so, but nevertheless the term is preferable to "acrodynia," the name of an epidemic disease supposed to have attacked about 40,000 persons during 1827-28 at Paris. The two diseases can hardly be the same, and yet the article by Dr. W. Weston on the new disease in Abt's *Pediatrics* (vol. ii, p. 986) has been headed "acrodynia," and cases have recently been exhibited under that heading at the Paris Société de Pédiatrie, and at the Lyon Société Médicale des Hôpitaux and at the London Royal Society of Medicine (Section for the Study of Disease in Children). Cases of erythroedema should not be permitted to masquerade under the term "acrodynia" any more than under "erythromelalgia," though symptomatically the latter term is a good one, signifying the presence of redness and pain in the extremities.—I am, etc.,

London, W.1, Jan. 15th. F. PARKES WEBER.

MIGRAINE AND ACETONURIA.

SIR,—The letters by Dr. Fawkes, "Consulting Surgeon," and Dr. P. J. Cammidge on this subject are most interesting, but to me they contain a contradiction, equally interesting—namely, that sugar deficiency is the cause, and that glucose is the proper treatment of migraine.

I also suffered for years from migraine, characterized by hemicrania (usually over the left eye, and relieved by

pressure upon the eyeball), nausea, and depression, and then vomiting of sour material. After vomiting and sleep the attacks passed away, but recurred about once or twice a week. I lived very plainly and used no alcohol, but I took sugar, treacle, and jams to excess. On stopping these the attacks ceased. I have for long taught that sugar in excess is the cause of "sick headaches," and I think two of my surgical colleagues in Newcastle can testify that cutting out sugar relieved them also of hemicrania.

In the out-patient department of the Royal Victoria Infirmary I have often seen middle-aged women complaining of "bilious attacks." When I asked one of these patients how much tea she drank, she would admit two cups for breakfast, one in the morning, one after the mid-day meal, two in the afternoon, and two for supper—that is, eight cups of tea daily. I then asked how much sugar she took in her tea, and the answer usually was two or three teaspoonfuls, with sweetened condensed milk in addition, say, thirty teaspoonfuls of glucose daily.

Now the sugar standard of Nature is the sweetness of milk, and a baby or young animal can grow and thrive on the proportion provided therein. And, rightly or wrongly, I consider most cases of migraine are due to sugar excess in adults, and particularly in thin persons, who are unable to convert sugar into fat, and who possibly produce lactic acid, which, irritating the nerve endings in the stomach, produce the reflex which we name migraine.

The reflex may, of course, come from quite different irritants, such as the fats, coffee, and whisky of "Consulting Surgeon," just as the nasal reflex of asthma may come from different irritants, and just as the reflex of epilepsy may come from gastric irritation, from a tight prepuce, an undescended testicle, or from the onset of puberty in girls. But among the irritants setting up migraine, I venture to think that sugar in excess is one, and commoner than is perhaps generally thought.

This seems contradicted by Dr. P. J. Cammidge's experience; he states: "If the blood is also examined an abnormally low sugar content is generally found, thus accounting for the beneficial effect of glucose to which Dr. Fawkes refers." I wonder what the explanation really is? Does a large intake of sugar mean improper assimilation, with the formation of acetone, lactic acid, or other irritant?—I am, etc.,

Newcastle-on-Tyne, Jan. 1st. T. M. ALLISON.

CHOLECYSTOGRAPHY.

SIR,—With reference to Professor Evarts Graham's letter (January 1st, p. 41), as I have been associated with Mr. Huddy in this work, I beg leave to point out that his reason for publishing this case was, not to criticize the methods of Professor Graham, but further to bring out the advisability of the drug being given in small doses and in two portions in preference to a single dose. Although as large doses have been given by other observers without fatality, they cannot, in view of this case, be considered without danger. The patient was particularly big and heavy, and as such might have been considered safe.—I am, etc.,

Birmingham, Jan. 11th A. RUSSELL GREEN.

MEDICAL POSTS IN INDIA.

SIR,—Under the heading "Medical posts in India" in the JOURNAL of January 15th (p. 120) "Observer" wisely advises intending applicants to consider carefully the terms offered; and not so wisely proceeds to criticize unfavourably the terms offered (JOURNAL, November 27th, 1926) by Lucknow University for the post of professor of anatomy. "Observer's" letter appears to me full of inaccuracies with regard to expenditure, and conditions of living in India generally; and on referring to the advertisement in the issue of November 27th I find that his statement regarding the terms offered is also inaccurate and misleading. He fails to state that the appointment would be temporary—about eighteen months—and that the salary for a permanent incumbent would be Rs.1,450-50-1,650; also that the deduction of 8 per cent. salary for the University Provident Fund—a wise form of insurance in India—would take effect only if the applicant were permanently appointed. With regard to the other two deductions mentioned:

(1) Income tax.—9 pies per rupee compares very favourably with 4 shillings in the pound sterling at home.

(2) Profession tax.—I am not familiar with this tax, which is stated to be not less than Rs.10 monthly.

With regard to cost of living, "Observer" (assuming the applicant to be a bachelor) states that "after exercising great and uncomfortable economy" the unfortunate professor might have a credit balance of Rs.300 a month; but that with a wife and family, involving a move to the hills during the hot weather, it would be impossible to live on the pay offered. The best answer to this is that scores of military officers and other Europeans in India manage to do it on a much lower salary. A bachelor living in the club, or in a "chummery," at such a place as Lucknow should be able to keep a motor bicycle or small car, play cricket, golf, tennis, and almost any game, except polo, and do himself reasonably well on Rs.600-800 a month. A great deal would, of course, depend on the size of his wine bill at the club.

I express no opinion as to whether or not a commencing salary of Rs.1,450 monthly (about £1,300 a year at present) is reasonable and adequate remuneration for a professor of anatomy in a provincial university in India, but at any rate it is a living wage. Finally, "Observer's" statement that living expenses in Calcutta are at least three times as much as in Lucknow is simply ridiculous.

I am aware that the cost of living in India, as everywhere else, has gone up tremendously, but "Observer" appears to take a much too gloomy view of the matter.—I am, etc.,

January 15th. LIEUTENANT-COLONEL (Ret.).

HISTORY OF DIPHTHERIA.

SIR,—A mere fleet surgeon should be in agreement with a surgeon-general, but when Sir Humphry *Rolleston* ascribes the discovery of diphtheria to Bretonneau in 1821 (JOURNAL of January 15th, p. 90) he traverses one of the traditions of my family, which holds, as have some other people, that diphtheria was first separately described, in 1765, by m[illegible] Francis Home, President of the Royal [illegible] of Edinburgh, 1775-77; and professor [illegible] in the University, 1768-98. In his essay on croup (1765) he mentions a false membrane in the larynx, and in his *Principia Medicinae* (third edition, 1770) speaks of the return of fluids through the nose in deglutition and the raw bleeding surface left if the membrane is pulled off, further recommending "bronchotomy" to prevent suffocation. His portrait is to be shown to the Epidemiological Section of the Royal Society of Medicine on January 28th.—I am, etc.,

W. E. HOME,
London, W., Jan. 15th. Fleet Surgeon.

ESSENTIAL OIL TREATMENT OF CHOLERA.

SIR,—I was much interested in Dr. Cannon's article on "The essential oil treatment of cholera" in your issue of January 15th (p. 98). Before I went to India in 1890 someone with experience of tropical disease advised me to use oil of cajeput in cholera. I was able to put this in practice during an epidemic of cholera among the European troops at Quetta, in the early nineties, with such good results that I determined to use cajeput again in any future cases I might have, but I did not again come in contact with cholera. Lapse of years must be my excuse for the lack of scientific detail in this very bald statement, but it is quite accurate as far as it goes.—I am, etc.,

E. C. FREEMAN, M.D.,
Bury St. Edmunds, Jan. 17th. Colonel, late R.A.M.C.

Obituary.

SIR ISAMBARD OWEN, M.D., F.R.C.P.,
Lately Vice-Chancellor of the University of Bristol.

WE regret to have to record the sudden death, in Paris on January 14th, of Sir Isambard Owen, who, during his residence in London, was an earnest worker for the British Medical Association.

Isambard Owen was the son of Mr. William George Owen, who became chief engineer of the Great Western Railway. He had been associated with Mr. Isambard Brunel in the construction of that railway, and when in 1850 his son was born was residing at Chepstow. His father afterwards removed to Gloucester, and Isambard Owen was sent to the King's School there and later to Rossall. He went up to Cambridge (Downing College) at the age of 18. Later on his old College made him an Honorary Fellow. Having resolved to take to medicine he entered the Medical School of St. George's Hospital, with which he remained connected until he left London. He was elected assistant physician and afterwards physician. He was dean for five years, and from 1899 lecturer on medicine until his appointment to be Principal of Armstrong College, Newcastle-on-Tyne, in 1904. He had graduated M.B.Camb. in 1876 and proceeded M.D. in 1882; in 1885 he was elected Fellow of the Royal College of Physicians of London.

Prior to his appointment at Newcastle Owen had shown a lively interest in higher education and had taken an active share in the discussions for the reconstitution of the University of London. Earlier than this he had been largely instrumental in the establishment of the University of Wales. While still a young man he had become a member of the great London Welsh Society of Cymmrodorion, and in 1879 became a member of its council; there then existed University Colleges at Aberystwyth, Bangor, and Cardiff, all in receipt of Government grants. Attention was first directed to intermediate education, and the Welsh Intermediate Education Act was passed in 1889. In 1887 Owen organized a public conference which passed resolutions disclosing a strong feeling in favour of the establishment of a national Welsh University, and it was at that early date recognized that women should be afforded the same facilities as men. In March, 1888, after a further conference of an academic character, held at Shrewsbury in January, a series of resolutions were laid before a meeting of Welsh peers and members of Parliament. In 1891 Isambard Owen was one of the representatives of Cardiff at a University Conference appointed by the University Colleges of Aberystwyth, Bangor, and Cardiff, and the Conference of Joint Education Committees. The difficult task of this conference was to frame a scheme which would commend itself to all these colleges, lay and academic elements alike, and to the rising intermediate education authorities, as well as to the religious bodies, the local authorities, and the general public of Wales. Something approaching unanimity was required to give any hope of success in getting a scheme passed into law. A draft scheme prepared by Isambard Owen and Principal Viriamu Jones was submitted to the conference, which laid down certain broad principles and provided for the appointment of a draft charter committee to prepare a scheme in detail. Of this committee, which began its meetings in April, 1892, Isambard Owen was an active member, and to him was entrusted the delicate and arduous duty of drafting a definite scheme. The University conference reassembled in January, 1893, adopted the scheme, remitted it to the county councils, the colleges, and the Intermediate Education Conference, and commended it to the public. For six months it was actively debated, but ultimately was found to have gained general assent. Both during and after this time an immense amount of work had to be done in defending the scheme and converting it into charter form; but Isambard Owen proved equal to all calls upon his time and energies, and the charter was approved by Parliament and passed under the Great Seal. Isambard Owen was appointed one of the Crown Members of the University Court, and when it met in April, 1894, he consented to act as honorary secretary till the statutes were completed and a registrar could be appointed. In January, 1895, Lord Aberdare was elected Chancellor, Principal Viriamu Jones entered office as first Vice-Chancellor, and Isambard Owen was elected Senior Deputy Chancellor. The Chancellor's place, when absent, is, in the University of Wales, taken by one of two deputy chancellors. The Vice-Chancellor is the academic head of the University, but not the chancellor's deputy unless specially elected as such. The vice-chancellorship can only be filled by the principal of a college. As originally contemplated, the duties of a deputy chancellor would have been limited to occasional presidency of the University Court or its committees, or of a congregation of the University, in the absence of a resident chancellor. The death of Lord Aberdare a few weeks later and the subsequent election of the then Prince of Wales (afterwards King Edward VII) to the chancellorship made the senior deputy virtually the acting head of the University in all but purely academic matters, and his office became an arduous and responsible one. He discharged all its duties with his accustomed grace and assiduity, and when he became officially connected with other universities he retained his connexion with Wales as a member of the council of University College, Cardiff, and a governor of University College, Aberystwyth. The honour of knighthood which he received in 1902 was a recognition of the work he had done for Wales in promoting the establishment of the national University.

SIR ISAMBARD OWEN.

Isambard Owen's chief contribution to the long-drawn-out discussions on the reconstitution of the University of London was a scheme for a University of Westminster, drafted in consultation with Sir James Fowler in 1897. It proposed to leave the existing University of London alone, and would have given to the medical schools all that they had asked for, and especially the possibility of their students obtaining a degree in medicine or surgery on terms of equality with students of other universities. It was, we are told, the twenty-first scheme which had been put forward. It differed from its predecessors by placing the chief power in the hands of a council of the faculty, the institutions represented therein being left to organize themselves, instead of entrusting this duty to a commission in the composition of which they had had no voice. A general committee was formed, containing 140 persons attached to one or other of the London medical schools,

and for a time the prospect of the scheme seemed good, but the London University Commission Bill was passed soon after the Westminster scheme was published in the BRITISH MEDICAL JOURNAL of December 25th, 1897 (pp. 1869-71), and it consequently went into abeyance and was never, so far as we are aware, revived. Owen loyally accepted the recommendations of the Royal Commission, and was vice-dean from 1901 to 1904 during Sir James Fowler's tenure of office as dean of the Faculty of Medicine of the University of London.

In 1904 he gave up his work in London to become Principal of the Armstrong College at Newcastle-on-Tyne.

Sir ROBERT BOLAM has been good enough to send us the following note:

Sir Isambard Owen's work in Newcastle-on-Tyne covered a brief period of five years. He followed Principal Gurney, and saw the finish of the construction and the official opening of the fine west front of Armstrong College. Probably through his personal influence King Edward and Queen Alexandra combined this function at the college with the opening of the New Royal Victoria Infirmary. Owen's great achievement in the Northern University, however, was undoubtedly the passing of the University of Durham Act in 1908. Before the successful issue of his diplomatic effort the place of Armstrong College in the University scheme was relatively subordinate. By the new Act Newcastle, with its College of Medicine and Armstrong College, became equally with the colleges at Durham represented in the administrative mechanism of the University The course of the negotiations themselves and the final achievement were remarkable tributes to Owen's genius for organization.

In 1909 he was appointed Vice-Chancellor of the newly constituted University of Bristol. The University had been formed by the combination of three institutions—a university college, a technical college, and the old-established medical school. Of the value of his work for the University Professor J. A. NIXON of Bristol has been good enough to send the following estimate:

Sir Isambard Owen came to Bristol as Vice-Chancellor of the University in its opening years. His mark had already been made in the academic field by his administration of the Armstrong College in Newcastle-on-Tyne and his strong hand in the University of Wales. He found several difficult situations to negotiate in those early years. They were not of his making, and he faced them with a striking detachment, which proved of the utmost value when the troubles had been overcome. It was a great factor in producing an atmosphere of concord that the Vice-Chancellor, the principal officer of the University, had played no part in the transactions which led for a time to serious discord. His neutrality and impartiality strengthened his position for the future.

The young University owed a great deal to his knowledge of university affairs. He was in touch with the other universities of the kingdom, and in conference and congress it was no small asset that the spokesman for the newest university should be already known and capable of commanding attention. In his handling of Government departments there was something of a "wizardry" that may have been, like that of a recent Premier, his birthright—for Sir Isambard Owen was in some of his gifts unmistakably Welsh. It showed in his deep, melodious voice, in his power of oratory, which, though restrained, could alternate quickly between deep emotion and light humour. His education at Cambridge, and his professional life in London as a physician at St. George's, had bred in him a wide sympathy with the humanities as the basis of university education. Thus, in spite of the overpowering attractions of science to the undergraduate of a modern university, Owen strove vigorously and successfully for a place in the sun for the Faculty of Arts and polite learning in general. There was a good deal of the artist in him; pictures and music appealed warmly to him. With medical affairs he concerned himself scarcely at all. It seemed as though he felt that his retirement from the practice of medicine had deprived him of all claim to advise on matters medical in his own university, though he sat on the General Medical Council as its representative from 1910 until 1925. Many of his colleagues knew him as Worshipful Master of the St. Vincent Lodge of Freemasons in the Province of Bristol. He was an ardent Freemason, and in the chair of his Lodge he won lasting affection and widespread admiration; he attained to high honours in the Province in recognition of his labours and his talents. Although at times in his later years he seemed frail and weary, and even ill, he never appeared old. He had a very young heart in him, so that when news came that he had died suddenly in Paris, at the age of 76, the realization of the full tale of his years could scarcely overcome the feeling that the end had come unexpectedly young.

The British Medical Association had from its first institution desired to contribute to the advancement of medicine, especially on its clinical side, and suggestions had been made from time to time that it should enlist the interests of its many members in the collection of clinical and epidemiological information. When, therefore, in his address as President of the Annual Meeting at Cambridge in 1880, Professor (afterwards Sir) George Murray Humphry dwelt on the undeveloped capacities for good collective work which the Association possessed, described the advantages which might be expected to accrue from the successful utilization of those capacities, and made a definite suggestion, it was at once accepted, and on the motion of the then Chairman of the Committee of Council, seconded by Mr. (afterwards Lord) Lister, a committee was appointed to consider how it might best be carried into effect; on its recommendation a Collective Investigation Committee was appointed at the next Annual Meeting (Ryde, 1881). The plan had a very good send off, for it was warmly supported at a meeting of the Metropolitan Counties Branch in the autumn of 1880 by Sir William Gull and Sir James Paget. Its first secretary was Dr. Mahomed of Guy's Hospital; after a couple of years he was succeeded by Dr. (now Sir) Wilmot Herringham, and he by Sir Isambard Owen. The committee worked very energetically and issued a large number of inquiry forms. Reports founded on these returns were prepared, one by Sir George Humphry on centenarians, another on chorea by Sir Stephen Mackenzie, and yet another by Sir Henry Butlin on cancer of the breast. Isambard Owen's own contribution was on the connexion of disease with habits of intemperance; it was published in this JOURNAL in June, 1888, and reprinted in the *Collective Investigation Record* which the committee had instituted. His conclusions were that habitual indulgence in alcoholic liquors beyond the most moderate amount had a distinct tendency to shorten life, and that of men who had passed the age of 25 the strictly temperate, on the average, lived at least ten years longer than those who become decidedly intemperate. Another conclusion was that alcoholic excess or the gout which it induced probably plays a special part in the etiology of chronic renal disease. The report expressed regret that the returns to the inquiry were not far more numerous than they actually were, and it has to be confessed that the scheme generally did not fulfil the high hopes which had attended its birth.

Isambard Owen was an active member of the Association while he continued to reside in London. He was one of the honorary secretaries of the Metropolitan Counties Branch from 1892 to 1897, and its representative on the Central Council from 1895 to 1899. He was one of the honorary local secretaries of the London meeting in 1895. He was a member of the Parliamentary Bills Committee from 1894 to 1897, and of the Medical Charities Committee from 1899 to 1902. He had been secretary of the Section of Medicine at the Annual Meeting in Birmingham in 1890, was vice-president of that Section at the Annual Meeting at Nottingham in 1892, and its president at the Annual Meeting at Swansea in 1903.

Isambard Owen was a good friend and a charming companion. Slim and rather frail in appearance, he was capable of withstanding fatigue, whether physical, in his favourite pastime of cycling, or mental, when completing under pressure some of the laborious inquiries he undertook. He formed opinions only after full examination, but then held them tenaciously. His manner was always conciliatory, but opponents of a different temperament were often surprised how trenchant could be his criticisms, uttered in a quiet tone and often illuminated by a flash of humour.

Sir Isambard Owen married in 1905, and is survived by Lady Owen and two daughters, to whom, on behalf of the Association and the profession at large, we desire to offer our sympathy.

THOMAS CLAYE SHAW, B.A., M.D.Lond., F.R.C.P.,

Emeritus Lecturer on Psychological Medicine, St. Bartholomew's Hospital.

THE death of Dr. Thomas Claye Shaw, in his eighty-sixth year, removes from the medical profession a remarkable personality. Dr. Claye Shaw was educated at King's College, London, where he was Senior Warneford Scholar. He became B.A. of the London University in 1860, M.R.C.S. and L.S.A. in 1864, and M.B. in 1866. He took the degree of M.D. in 1867, qualifying for the gold medal, and in 1880 was elected a Fellow of the Royal College of Physicians. Turning his attention to mental disease, he became medical superintendent of the London County Asylum at Banstead, in Surrey. Subsequently he was appointed lecturer on psychological medicine at St. Bartholomew's Hospital, and lecturer on clinical insanity at St. Luke's Hospital in the City. At one time he was examiner in mental physiology and psychological medicine at the University of London, and to the Board of Studies of the Army Medical Service. With the Rev. H. Hawkins he took an active and early part in the foundation of the After-Care Association. Dr. Claye Shaw was an ex-president of the Society for the Study of Inebriety, and a member of the Medico-Legal and the Harveian Societies. He was associated with the Psychological Section of the British Medical Association as honorary secretary at Manchester in 1877, as vice-president in London in 1895, and as president at Exeter in 1907.

Dr. Claye Shaw was rugged in appearance, and rugged also, though kindly, in manner. He was, perhaps, one of those who want knowing; but to those who knew him he was kindness itself, helpful in an emergency, and of sound judgement on all occasions. As a lecturer he was very attractive, and his classes at St. Bartholomew's Hospital were always well attended. He was outspoken, and dogmatic as far as his subject would allow. Those who were at the hospital in the nineties will remember an occasion on which he gave the opening address at the Abernethian Society. He came prepared with an address "for men only." He was startled, but unabashed, at finding a mixed audience of students and nurses.

Most of Dr. Claye Shaw's writings were articles in journals, hospital reports, and medical dictionaries. But he wrote one book, *Ex Cathedrâ Essays on Insanity*, which we reviewed in December, 1904. In that review attention was called to Dr. Claye Shaw's breadth of view and originality, to the illuminating character of this Book as a psychological study of insanity, and to the useful provocativeness of theories wherein he was at variance with other authorities. In 1913 Dr. Claye Shaw aroused much discussion by an address to a medical audience. He warned the modern woman that her new activities in sport and independence in life would mar the beauty of her face, change her nature, and alienate male sympathy. At the beginning of the war he made a scathing attack on the mentality of the German in general and the Kaiser in particular. In an article on the psychology of sport he displayed his keenness for this form of mental relaxation by advocating the setting up of public memorials to all outstanding figures in the world of sport.

Dr. Claye Shaw was virile and robust in mind and body, with, perchance, a tinge of genial eccentricity acquired from long contact with the insane. Latterly, those who knew him well, and admired his great qualities, had seen little of him. He lived in retirement at Cheltenham with his wife, who predeceased him by less than two years. He had two daughters.

We regret to announce the death of Mr. FREDERICK GEORGE LARKIN of Grove Park, Kent, in his 80th year, on January 13th. Mr. Larkin received his medical education at Guy's Hospital and obtained the diplomas M.R.C.S.Eng. in 1870 and the L.R.C.P.Edin. and L.M. in 1882. He early attracted notice as a pioneer in surgery, for in 1869 he read a paper before the Guy's Hospital Physical Society, in which he suggested excision of the kidney as the result of some careful practical research he had already accomplished. This paper aroused considerable interest and paved the way for the first operative measures at Guy's Hospital and elsewhere for the treatment of stone in the kidney and other renal diseases. In 1915 he was elected to the Fellowship of the Royal College of Surgeons of England as a member of twenty years' standing. Mr. Larkin became known also in medico-legal circles in consequence of his connexion with the Whitechapel tragedy, and published the report of the *post-mortem* examination on Harriet Lane (JOURNAL, vol. ii, 1875, p. 730). In the next year he gave evidence as principal witness for the Crown in the celebrated Wainwright case, and was congratulated on his careful examination and lucid account. He won widespread popularity as a general practitioner, taking a special interest in renal and general surgery and the treatment of fractures. Apart from his surgical work, his chief recreation was music, and particularly Church music. He served as choirmaster in two churches successively, and for many years was closely associated with the Westminster Abbey choir, in which he sang at the jubilee celebrations of Queen Victoria and the coronation services of King Edward VII and the present King. His musical compositions include a dramatic song "The Shipwreck" and various pieces of Church music. He was buried at Heath near Canterbury, where he was born.

Dr. HENRY BERTRAM DISMORR, who died at Hallidays, Purton, on January 4th, was a son of Dr. Henry Dismorr, formerly of Lewisham. He was educated at Clifton and Guy's Hospital, obtained the diplomas M.R.C.S., L.R.C.P. in 1900, and after a two years' appointment as assistant medical superintendent at Lewisham Infirmary and medical officer of Lewisham Workhouse, commenced practice at Wroughton, Swindon, where he was much respected by his colleagues. For upwards of twenty years he struggled, with occasional breakdowns, against the pulmonary disease which led to his retirement in 1922, at the age of 45. Dr. Dismorr took a keen interest in all sports, and was a prominent Freemason. He was honorary secretary of the Swindon Division of the British Medical Association from 1914 to 1923, and member of the executive committee from 1915 to 1923. He was also a member of the Wiltshire Branch Council from 1915 to 1923. He leaves a widow and one daughter.

Dr. WILLIAM POWER EVERARD, who died on January 2nd, at his residence in Athlone, obtained the diplomas L.R.C.P., L.R.C.S.Edin., and L.R.F.P.S.Glasg. in 1889. He was first appointed medical officer of the Brideswell dispensary district, and was subsequently transferred to Glasson. For the last eighteen years he had been in charge of a dispensary district in Athlone, where his unfailing kindness won him numerous friends. He was on the staff of the St. Vincent Hospital, Athlone.

The Services.

NAVAL MEDICAL COMPASSIONATE FUND.

At the quarterly meeting of the directors of the Naval Medical Compassionate Fund, held on January 18th, when Surgeon Vice-Admiral Sir Joseph Chambers, K.C.B., C.M.G., Medical Director-General of the Navy, was in the chair, the sum of £135 was distributed among the several applicants.

R.N.D.S.

At the recent competitive examination of candidates for entry into the Royal Naval Dental Service, the undermentioned were successful: W. E. L. Brigham, L.D.S., L. F. Fairey, L.D.S., S. Mawer, L.D.S., F. D. Manners, L.D.S., L. A. Moules, L.D.S., G. Baker, L.D.S., W. C. G. Ford, L.D.S., L. R. Armstrong, L.D.S., H. M. Hill, L.D.S. The names are given in the order of merit shown at the examination.

AMALGAMATION OF NURSING SERVICES.

THE Queen Alexandra's Imperial Nursing Service and the Queen Alexandra's Military Families' Nursing Service have been amalgamated by a Royal Warrant. The combined nursing service will be named "Queen Alexandra's Imperial Military Nursing Service," and its members will wear the same uniform and badge as at present exist for the Q.A.I.M.N.S.

Universities and Colleges.

ROYAL COLLEGE OF SURGEONS OF ENGLAND.

A QUARTERLY Council meeting was held on January 13th, when the President, Sir Berkeley Moynihan, Bt., was in the chair.

Honorary Fellowship.

The President reported that H.R.H. Princess Mary, Viscountess Lascelles, had consented to become an honorary Fellow of the College. The President also stated that Princess Mary hoped to attend at the College on Monday, February 14th, to hear the Hunterian Oration, and that there would then be a suitable opportunity for presenting the diploma to Her Royal Highness.

Lister Centenary Celebrations.

Sir Berkeley Moynihan was nominated to represent the Royal College of Surgeons of England at the celebration in London of the centenary of the birth of Lord Lister, which falls on April 5th, 1927.

Appointments.

Mr. Thelwall Thomas was re-elected to represent the College on the Court of Liverpool University.

Mr. E. Rock Carling, Mr. A. E. Webb-Johnson, and Mr. Claude Frankau were introduced and admitted members of the Court of Examiners.

Diplomas.

Diplomas were granted jointly with the Royal College of Physicians: In Public Health, to twenty-six candidates; in Psychological Medicine, to ten candidates; in Laryngology and Otology, to seven candidates.

The diploma of Fellowship was granted to one candidate, the diploma of Membership was granted to three candidates, and the Licence in Dental Surgery was granted to one candidate, these having now complied with the regulations.

Medico-Legal.

A DUBLIN SURGEON'S FEES.

AN action was heard recently in the High Court in Dublin by Mr. Justice Hanna in which Mr. Denis Kennedy, F.R.C.S.I., a well known Dublin surgeon, claimed £1,468 from the executors of the will of Susan Fay, for work done and services rendered by the plaintiff as a medical practitioner for the deceased, a widow, who had resided at Sandymount, Dublin. The defendants pleaded that the plaintiff did not render the services alleged, and said that the fees charged were not agreed fees, and they were exorbitant and unfair. While denying any liability, the defendants brought into court the sum of £526, which they said was sufficient to satisfy plaintiff's claim. The deceased, it appeared, was operated upon several times by the plaintiff, and otherwise attended at a private hospital and at her own residence before her death.

The plaintiff gave evidence, and outlined the nature of the operations and his subsequent work for the deceased in hospital and at her home. He said that his charges were reasonable. If she had been a very wealthy woman he might have charged more. In cross-examination, the witness said that he never brought a patient into court. Asked what was the highest fee that he had ever received for an abdominal operation, he replied that he once received 400 guineas for an operation and attendance in hospital afterwards. A hundred guineas was not an exorbitant fee for an abdominal operation if the patient was fairly well off. He was in attendance on this lady for nearly two years. He never sent his account to the deceased, as she never asked for it, but she said his fees would be all right. Mr. J. S. McArdle, F.R.C.S.I., gave evidence; he said that the usual fee for operations of this kind was 100 guineas, but it was not the maximum fee. He would not like to take it at anything less than Mr. Kennedy took. The witness said that he had performed 2,000 operations similar to this one. He had received payment for about 25 per cent. of them. His minimum fee for such an operation was 50 guineas. Mr. R. C. B. Maunsell, F.R.C.S.I., said that these were full fees, but certainly not excessive. Asked if it was not usual to send a bill before the patient died, witness said that in some cases it was kind not to do so.

Mr. Fitzgerald, K.C. for the executors, said that they had found it impossible to give the court the expert evidence that was expected. Notwithstanding every effort made by the executors and their solicitors to procure the attendance of a surgeon in Dublin or Belfast, not one of them could be got who would go into the box and tell the court what, in their opinion, was the value of plaintiff's services. The plaintiff's income in fees from this patient worked out at practically £1,000 a year. The executors had met the demand by bringing into court a substantial sum, beyond which they did not think they should be asked to pay. A good deal had been made of what was called the standard fee of a surgeon, but counsel would define it as being what the hope of life would wring from a patient.

In giving judgement for plaintiff for the sum of £680 and costs, Mr. Justice Hanna said that he was bound to take into consideration that the plaintiff was in the first rank, and exercised the very highest degree of surgical skill. He was also bound to consider the position in which Mrs. Fay was. She was a lady who had come into the bulk of her estate through a second marriage, and lived in moderate circumstances in Sandymount. He had nothing but commendation for the executors, who, when faced with a claim which they thought exaggerated, submitted to the court. That was the best way for executors to protect themselves from criticism, and equally Mr. Kennedy had no alternative but to come into court. The amount might have been left to some eminent surgeon to decide, but it was equally possible that it would be difficult to get a medical man to decide as between a colleague and an outsider. He was not inclined to cheesepare with Mr. Kennedy, and, accordingly, in respect to the first three operations, he awarded the fees of £100 for the first operation, £75 for the second, and £50 for the third. It had been argued that the attendance after operations should be complimentary, but, having regard to the evidence, his lordship thought that there was a good deal more to be done than mere normal attendance and examination. Attendance would be covered by £75 in respect of the first three operations. There were six minor operations, for which he awarded £15 each; for attendance during four months, £40; attendance at the deceased woman's residence at Sandymount during seven months, £100; for the Leeson Street Home operation, £75, and treatment and attendance, £50, and to cover general attendance, £25.

Medical News.

THE Hunterian Oration before the Royal College of Surgeons of England will be delivered at the College by Sir Berkeley Moynihan, Bt. (President), on Monday, February 14th, at 4 p.m.

A DISCUSSION on the treatment of cleft palate will be held at the Section of Surgery of the Royal Society of Medicine on Wednesday, June 1st, at 5 p.m. Sir James Berry will open the discussion and will be followed by Mr. Grey Turner and a large number of other surgeons. All speakers are invited to present statistics and show cases to demonstrate the result as to speech.

THE following promotion and appointments to the Order of the Hospital of St. John of Jerusalem are announced. *As Knight of Justice (from Knight of Grace):* Major Sir John Lumsden, K.B.E., M.D. *As Knight of Grace:* Lieut.-Colonel E. J. T. Cory, O.B.E., T.D., M.D. *As Officers (Brothers):* Dr. Marcus A. J. de Lavis-Trafford, O.B.E., Dr. A. R. McLeod, Colonel R. A. Needham, C.I.E., D.S.O., I.M.S., Dr. Louis Patrick Stokes, Major Hugh T. Galbraith, Dr. Robert D. A. Douglas, M.B.E.

TWO sets of post-graduate courses have been arranged at the Royal Northern Hospital for the current year. Course I is open to all practitioners free of charge. It consists of weekly lectures or demonstrations on Tuesdays at 3.15 (the next being on January 25th by Dr. Malcolm Donaldson on salpingitis); and of intensive courses, each lasting a week, to be held in February, May, and October. Tea is provided on each occasion. Course II, on recent advances in medicine, and suitable for the M.R.C.P. and other higher examinations is held thrice yearly at a charge of five guineas; the next will be during the first fortnight in March. Further particulars may be obtained from the Dean, Dr. E. G. Calvert, Royal Northern Hospital, Holloway Road, N.7.

A NEW series of post-graduate clinics arranged by the University of Sheffield commenced on January 14th, when Dr. Wilkinson discussed cerebral complications of middle ear suppuration. The meetings are held at the Royal Hospital, Sheffield, and are open to all qualified medical practitioners without fee; they will be continued on Fridays, at 3.30 p.m. until March 25th.

A POST-GRADUATE course on diseases of the nervous system will be held at the National Hospital, Queen Square, from January 31st to March 25th. It will include clinical lectures, out-patient work, and demonstrations, and the fee will be five guineas. A course of lectures on the anatomy and physiology of the nervous system will be arranged if there are sufficient applicants. A special course of clinical demonstrations on methods of examination of the nervous system will also be given. Further information may be obtained from the Secretary of the Medical School, National Hospital, Queen Square, W.C.1.

FOUR lectures on a survey of the public health, based on the report for 1925 of the Chief Medical Officer of the Ministry of Health, will be delivered by Sir Robert Armstrong-Jones at Gresham College, Basinghall Street, E.C.2, on January 25th, 26th, 27th, and 28th, at 5 p.m. *Admission to the lectures* is free to men and women.

THE lecture to the congress of the Royal Sanitary Institute to be held at Hastings next July, will be given by Sir W. H. Willcox, K.C.I.E., M.D., on chronic rheumatism in its relation to industry. The congress will have six sections, and there will also be seven conferences.

THE third annual Sims Woodhead Memorial Lecture will be delivered in the Arts School, Benet Street, Cambridge, on Thursday, January 27th, at 5.15 p.m., by Mr. W. McAdam Eccles, M.S., F.R.C.S. His subject is "Alcohol in the light of modern research: points accepted and disputed." The Vice-Chancellor of the University will preside. Seats will be reserved on the 3 p.m. train from King's Cross.

THE Fellowship of Medicine announces that on January 27th the opening lecture of the new series on emergencies in medicine and surgery will be delivered by Dr. Burrell on hæmoptysis, at 5 p.m., at 11, Chandos Street, Cavendish Square. On January 25th Mr. Victor Bonney will give a demonstration at the Chelsea Hospital for Women, at 2 p.m. From January 31st for four weeks the London School of Dermatology (St. John's Hospital) will hold a clinical course in dermatology; classes in pathology can be arranged. From February 7th the London Lock Hospital will give a four weeks' clinical course in venereal diseases and a series of lectures. Also starting on this date there will be a combined two weeks' course in diseases of children in which the Paddington Green and Victoria Hospitals are participating. The Fellowship also organizes courses in obstetrics and anæsthetics, and can arrange appointments as clinical assistants at the Samaritan Hospital. Copies of all syllabuses, the *Post-Graduate Medical Journal*, and the programme of the general course can be obtained from the Secretary of the Fellowship of Medicine, 1, Wimpole Street, W.1.

THE programme of the Post-Graduate Hostel, Imperial Hotel, Russell Square, W.C.1, for next week includes an address, on Tuesday, by Professor C. C. Choyce, on pre-Listerian surgery, and a discussion, on Thursday, on the thyroglossal tract. Dinner (5s.) will be served each day at 8 p.m., and the meetings begin at 9 o'clock. All medical practitioners are welcome.

THE Child Study Society, London, has issued its syllabus of lectures and discussions for 1927. At the meeting on March 17th a paper on "Completion of the education of the parent" will be communicated by Dr. J. R. Rees, with the President of the society (the Hon. Sir John A. Cockburn, K.C.M.G., M.D.) in the chair. At the annual meeting on April 28th a discussion on problems in the upbringing of children will be opened by Dr. J. Norman Glaister. Both meetings will be held at 6 p.m., at the Royal Sanitary Institute, 90, Buckingham Palace Road, S.W., at which address full particulars of the society can be obtained on writing to its secretary, Miss H. M. Richards.

A MEETING of pathologists attached to various London and provincial hospitals was held at the London School of Medicine for Women on January 7th, when it was decided to form a society entitled the British Pathologists Association, to develop the application of pathology in relation to medicine, and to protect all those engaged in its study and practice. It was agreed that membership should be open to all registered medical practitioners engaged in pathological work; the annual membership fee was fixed at one guinea, no entrance fee being required. Dr. C. Powell White of Manchester was appointed president of the new association, and Dr. S. C. Dyke of Wolverhampton, secretary.

ON his retirement Dr. John R. Staddon, after forty years' service as medical officer to the Ipswich Board of Guardians, was entertained by the past and present staff at Heathfields at a farewell supper, and presented with a Sheraton dining table and an illuminated address, together with a cut-glass cigarette bowl from the patients in the infirmary.

DR. AND MRS. D. J. THOMAS of Portheawl have been presented by the inhabitants of Nantymoel with a silver tray and entrée dishes and a wallet of notes as a mark of esteem for the services rendered by them during the past forty years.

DR. CHARLES SINGER'S second lecture on the "History of medicine" will be given at the College of Medicine, Newcastle-upon-Tyne, on Friday, February 11th, at 4.45 p.m. All medical practitioners in the neighbourhood are invited to attend.

SIR JOHN HERBERT PARSONS has written *An Introduction to the Theory of Perception*, which will be published by the Cambridge University Press next month in the Cambridge Psychological Library, the series in which his earlier work on colour vision also appeared.

THE Sollux Publishing Company, Slough, has published translations in English of Rost's *Biological Basis of Ultra-violet Therapy*, Jesionek's *Light as Stimulus*, and Bach's *The Treatment of Wounds*, all at 1s. It has also published in English Huldschinsky's *The Ultra-violet Light Treatment of Rickets*, at 6d., and Heusner's *Light Therapy in Pulmonary Tuberculosis*, at 1s. 6d.

THE nature and properties of acriflavine have been fully reported upon in the BRITISH MEDICAL JOURNAL; in fact, they were, we believe, first described by Professor C. H. Browning of Glasgow and his colleagues in our columns. The British Drug Houses, Ltd. (16, Graham Street, City Road, London, N.1), have now put on the market preparations in solution, tablet, and other forms, for the use of medical practitioners. The same firm also supplies euflavine and roflavine.

THE Kaiser Friedrich Hospital at San Remo, which is primarily intended for visitors to the Riviera, was reopened at October under a staff of German physicians.

A PLAY entitled *La Vocation*, which is the joint work of André Pascal (Dr. Henri Rothschild) and Professor Pierre Delbet, has recently been performed at the Théâtre de la Renaissance in Paris.

FROM the French census, taken on March 7th last, it appears that the population of France was 40,743,851 on that date, as compared with 39,209,666 in 1921. But out of this increase of 1,500,000 in five years less than half a million were great that in some areas they form a very substantial proportion of the population. Thus in the department of the Seine one-tenth of the inhabitants are foreigners; in Seine-et-Oise one-thirteenth; while in the Alpes-Maritimes no-less than one-third of the population is foreign.

DURING September four cases of plague were notified in Guayaquil, and 21,233 rats were caught, 30 of which were infected.

A FRANCO-DUTCH Scientific Committee has recently been formed as an independent section of the centre for Franco-Dutch studies at Paris. The new committee consists of French and Dutch subsections. In the Dutch subsection physiology is represented by Professor J. J. A. Buytendijk, medicine by Professor A. A. Hijmans van den Bergh, and bacteriology by Professor P. C. Flu.

THE Bureau of the Far East at Singapore reports that for the week ending December 25th there were 21 cases of plague with 10 deaths, 296 cases of cholera with 276 deaths, and 304 cases of small-pox with 79 deaths.

TWO persons, one of whom was the well known physician Professor Ellermann, have recently died of anthrax at Copenhagen after using infected horse-hair shaving brushes.

Letters, Notes, and Answers.

All communications in regard to editorial business should be addressed to **The EDITOR, British Medical Journal, British Medical Association House, Tavistock Square, W.C.1.**

ORIGINAL ARTICLES and LETTERS forwarded for publication are understood to be offered to the BRITISH MEDICAL JOURNAL alone unless the contrary be stated. Correspondents who wish notice to be taken of their communications should authenticate them with their names, not necessarily for publication.

Authors desiring REPRINTS of their articles published in the BRITISH MEDICAL JOURNAL must communicate with the Financial Secretary and Business Manager, British Medical Association House, Tavistock Square, W.C.1, on receipt of proofs.

All communications with reference to ADVERTISEMENTS, as well as orders for copies of the JOURNAL, should be addressed to the Financial Secretary and Business Manager.

The **TELEPHONE NUMBERS** of the British Medical Association and the BRITISH MEDICAL JOURNAL are *MUSEUM 9861, 9862, 9863, 9864* (interna' exchange, four lines).

The **TELEGRAPHIC ADDRESSES** are:
EDITOR of the BRITISH MEDICAL JOURNAL, *Aitiology Westcent, London.*
FINANCIAL SECRETARY AND BUSINESS MANAGER (Advertisements, etc.), *Articulate Westcent, London.*
MEDICAL SECRETARY, *Mediocrity Westcent, London.*

The address of the Irish Office of the British Medical Association is 16, South Frederick Street, Dublin (telegrams: *Bacillus, Dublin*; telephone: 4737 Dublin), and of the Scottish Office, 6, Drumsheugh Gardens, Edinburgh (telegrams: *Associate, Edinburgh*; telephone: 4361 Central).

QUERIES AND ANSWERS.

"F. J. B." asks for suggestions for the treatment of a baby, aged 6 weeks, suffering from burns (now healed) of third degree on face, with a view to preventing contractures and scarring.

INCOME TAX.

Appointment: Expenses.

"D. W. T." held a hospital appointment from February to October, 1922; his earnings from April 5th to October, 1922, were £198 10s., and he is asked to pay £6 10s. for 1922–23. Can he claim any relief, especially as regards expenses consequent on illness occurring in that year?

*** The tax payable for 1922–23 appears to be as follows:

	£	s.	d.
Salary	198	10	0
Deduct one-tenth earned income relief	19	16	6
Assessable income (say)	179	0	0
Personal allowance	135	0	0
Income chargeable to tax	44	0	0
Tax due thereon at 2s. 6d. in the £ = £5 10s.			

"D. W. T." cannot claim to average his earnings for purposes of assessment, and the expenses to which he refers are not allowable.

LETTERS, NOTES, ETC.

MATERNAL MORTALITY.

"F. U." (Cornwall) writes: It is distinctly amusing to read that "the great lights" of the English obstetrical world are only now grasping an elementary fact which was taught over twenty years ago at the Rotunda Hospital, Dublin. Hastings Tweedy's great dictum then was, "the great thing to teach is not how to put in forceps, but *when* to do so"—namely, distress on the part of the mother or foetus as shown by pulse and temperature, and not for the mere sake of shortening labour. Provided doctors will keep these instructions in their midwifery bag and read them before each confinement, I do not deplore the so-called lack of self-reliance exhibited by some nurses which Dr. Fairbairn seems to regret. A nurse cannot always be certain of an occipito-posterior position, and I do not believe the man who states he can be always certain of that position without an examination under an anaesthetic. Provided the general practitioner is properly taught when a student, which he certainly does not seem to be—at least in England—and provided he is keen on the work and that the local hospitals will let him have the use of a bed should he require it, a great deal would be accomplished. This last point seems to be very hard to manage on account of the "closed door" policy of most hospital staffs, though in many cases the men on the staff frankly state they are interested in surgery, not midwifery, and do a very small midwifery practice, though general practitioners themselves. I claim to speak with some experience; I have been at work for twenty years, but, except for Caesarean section, I have never sent a case to hospital. I have had practically every emergency that can crop up; I averaged eighty cases each year for the last eight years, and in twenty years I have had one maternal death—a case of placenta praevia to which I was called by another doctor when the patient was moribund from haemorrhage. Railing at the general practitioner will get us nowhere. In Dr. Fairbairn's book there is much contradiction by the various authors in their choice of treatment, and certainly treatment is advocated which is, to put it mildly, questionable. I refer to the giving of 1 c.cm. of pituitrin in face presentation. Let me forestall critics and say that I never perforate unless in case of a hydrocephalic or when the foetus is dead or the mother placed in a serious position by well meant but futile efforts of somebody who has tried to drag "a highly impossible head through a highly impossible pelvis."

DR. JAMES COOK (Dennistoun) in a letter on this subject writes: I have read Dr. Fairbairn's article (p. 47) with great pleasure, but I am astonished by the figures as to the mortality at the East End Mothers' *Lying-in Home*. The *forceps delivery rate* would suggest that it is specially blessed with normal cases. And a total death rate of 1 in 1,500 with not a specialist to take the credit of it is hard to be believed. I think all practitioners will agree that there is no more heart-rending situation than that of a death in childbed. If an institution run by midwives is the solution of this problem let us provide these without delay, for such delay entails the needless loss of four mothers in every 1,000 births still attended by doctors. I would suggest that midwifery should cease to figure in the student's curriculum, that these cases should be attended by women only; then, being freed from the contamination of the man doctor, sepsis and death would cease altogether. The general practitioner would hang his forceps on the wall and study midwifery no more.

HERPES AND VARICELLA.

DR. T. COMPTON (Bognor) writes: I have just had the same experience as that quoted in the letters of Dr. Cyril Helm and Dr. R. Lynn Heard (January 15th, p. 124). On December 17th, 1926, an old lady of 76 developed well marked herpes zoster, beginning in the left dorsal region [illegible] front of the chest. On January 8 [illegible] aged 10, developed well marked [illegible] number of spots. This was particularly puzzling to me as I could trace no source of infection for the attack.

DR. FRED. W. GAVIN, Assistant M.O. Surrey County Council, writes: The following case is of interest in connexion with the alleged relation between herpes and varicella. On December 20th, 1926, a gardener developed herpes zoster ophthalmicus. On January 5th his three children—two girls, aged 8 and 9 years respectively, and a boy, aged 5—all showed definite chicken-pox. The source of this outbreak of varicella could not be traced apart from the above-mentioned herpes. It is interesting to note that the time between the herpes and chicken-pox is sixteen days. The children were seen by me at one of the school clinics.

A SKIN TEST FOR APPENDICITIS.

DR. A. COWAN GUTHRIE (London) writes to recommend a test which he has found useful in establishing a diagnosis of appendicitis in early and doubtful cases. A hypodermic syringe is filled with 1 c.cm. of anticoli vaccine (250 million to the cubic centimetre). The surface of the abdomen is sponged with methylated spirit, and over the right iliac region a few short scratches, rather more than half an inch in length, are made with the hypodermic needle, care being taken to penetrate only the superficial layer of the epidermis. A few drops of the vaccine are then ejected upon the excoriated surface. The same proceeding is carried out over the left iliac region with a sterilized empty hypodermic needle to act as a control. Within a few minutes, if the test be positive, a well marked inflammatory area shows around the excoriated surface on the right side, extending to rather more than an inch in circumference. This hyperaemic area stands out clearly defined in twenty-four hours, and may last from two or three days to a week. Dr. Guthrie adds that in all cases where a positive reaction occurred pathogenic *B. coli communis* was found in the faeces, and the clinical signs and subsequent history established the value of this test in suspected appendicitis.

TREATMENT OF INFLUENZA.

DR. ALEXANDER FRANCIS (London) writes: Now that influenza is so rife would you allow me to draw attention to the value of Dr. Carl Spengler's "Grippe I. K." Five drops taken in milk at the beginning of an attack will either cause it to abort or greatly modify its course. If the fever is high five drops rubbed on the flexor surface of the forearm (which Spengler claims is ten times more effective than drinking it) will quickly cause a reduction of the temperature. It has been proved to be of value in pneumonia supervening upon influenza. It can be obtained in this country from Messrs. Allen and Hanburys, Ltd.

COMMUNISM AND MALTHUSIANISM.

DR. B. DUNLOP (London, W.) writes with reference to the review (JOURNAL, January 8th, p. 62) of a book on communism: I doubt if the majority of communist leaders have included "eugenic selection for propagating the species" and "limitation of families" in their sociology. The first of these considerations clashes with their basic idea of equality; and as to the second, I know that leaders of the Soviet revolution in Russia scorned the Malthusian suggestion that a high birth-rate would cause a chronic food shortage even under their social system.

THE LABORATORY ASSISTANTS' ASSOCIATION.

HIGH ideals and steady work confer popularity as well as success [illegible] the growth of the Pathological and [illegible] Assistants' Association since its [illegible] 1912 was only to be expected. Its membership has now increased to 412, and the report for the year 1925–26 foreshadows further progress in several directions. Lectures and demonstrations arranged by the four divisions of the association in Great Britain and its component branches have been well attended, and the classes and discussions which deal with practical points in laboratory technique will undoubtedly benefit pathological research generally. Examinations for the certificates of the association were held in July in London, Manchester, Glasgow, and Cardiff, and the insistence on practical efficiency, rather than on theoretical knowledge, renders this side of the work of the association very valuable. It is announced that pathological chemistry will henceforth be one of the major subjects of examination. The competition for the two prizes provided by the fund raised in memory of Professor W. S. Greenfield attracted several papers and exhibits of high quality. The senior prize, of the value of £15, was won by Mr. E. C. Haddon, of Entebbe, Uganda, for a dissertation on the nature and origin of the enrichment principle in culture media. The junior prize was awarded to Mr. P. W. Powles, of Cambridge, for an exhibit of the isolation and cultivation of the bacteria composing the film on teeth. The Simon Woodhead prize this year will be given for the best essay on the ideals of a laboratory assistant. A conference will be held a [illegible] The official organ of the association— [illegible]—is issued quarterly and has been [illegible] from overseas are prominent, and, in addition to news and original articles, special attention is given to practical notes on laboratory technique and abstracts of articles in other periodicals. The employment bureau of the association is becoming increasingly useful, both to members and to pathologists generally. Valuable assistance has been rendered in various ways by the Pathological Society of Great Britain, the London School of Hygiene and Tropical Medicine, and the Wellcome Bureau of Scientific Research. Further information about the association may be obtained from the general secretary, Mr. H. Gooding, 10, Holbeck Grove, Victoria Park, Manchester.

WOMEN ON TEACHING HOSPITAL STAFFS.

DR. MARION GILCHRIST (Glasgow) writes: Mr. Norman M. Dott, F.R.C.S.E., has pointed out (January 8th, p. 86) that there has been a woman on the surgical staff of the Royal Edinburgh Hospital for Sick Children since May, 1925. May I say that we in the West have been even more progressive, as a woman—Dr. Katharine Mary Chapman—was appointed chief of the radiological department of the Glasgow Royal Infirmary in June, 1920, and also university lecturer, and held this appointment for several years.

A CORRESPONDENT, writing from Liverpool, informs us that Dr. Mona Roberts of that city was appointed honorary anaesthetist to the Royal Infirmary—a teaching hospital of the University of Liverpool—in 1914.

A DISCLAIMER.

DR. HAROLD DEARDEN (London, W.) writes: My attention has been drawn to certain references to myself in the press of a laudatory character. I wish to disclaim all responsibility for these notices and to state that I am doing all in my power to prevent their repetition.

VACANCIES.

NOTIFICATIONS of offices vacant in universities, medical colleges, and of vacant resident and other appointments at hospitals, will be found at pages 40, 41, 44, and 45 of our advertisement columns, and advertisements as to partnerships, assistantships, and locumtenencies at pages 42 and 43.

A short summary of vacant posts notified in the advertisement columns appears in the *Supplement* at page 27.

An Address
ON
THE MODERN TREATMENT OF HERNIA.

DELIVERED TO THE NORTH-EAST ESSEX DIVISION OF THE BRITISH MEDICAL ASSOCIATION, DECEMBER 3RD, 1926.

BY

GEOFFREY KEYNES, M.A., M.D.CANTAB., F.R.C.S.ENG.,
FIRST ASSISTANT, SURGICAL UNIT, ST. BARTHOLOMEW'S HOSPITAL;
SURGEON, CITY OF LONDON TRUSS SOCIETY.

THE treatment of hernia is a well worn subject, and one which cannot be dealt with to any purpose without introducing some technicalities. I dare to hope that even these will not prove uninteresting, since upon them depends the success or failure of the treatment of conditions which are seen so commonly by every practitioner of medicine or surgery. It can also be claimed that important advances in surgical treatment have been made in very recent times, and I may be able to bring to your notice methods which are still but little known. Although the subject is so well worn that surgery might be thought to have arrived almost at the point of final standardization, and that the results had been brought as near to perfection as might be, yet I have an uneasy feeling that we are rather further from attaining perfection than is commonly supposed, and that the economic loss to the community from the prevalence of all forms of hernia is still much greater than it ought to be.

Since 1919 I have worked at the City of London Truss Society in Finsbury Square, a charity which during the last 120 years has dispensed appliances for the treatment of hernia to some three-quarters of a million patients. We still see several thousand patients each year, but it is, of course, obvious that the advance of surgery has greatly reduced the need for the use of trusses. A large proportion of our patients are past middle age, for nearly all the younger patients now obtain treatment by operation at the hospitals. The very existence of trusses is to some extent a confession of surgical failure, but I think there will always be some scope for their use, although it will contract year by year. It is my experience at the Truss Society which has given me the slight uneasiness already mentioned. An apposite story is related of John Langton, one of my distinguished predecessors in Finsbury Square. The incident took place at a meeting of the Royal Medical and Chirurgical Society, a precursor of the Royal Society of Medicine. A discussion turned on the results of the operation for the cure of hernia, and a surgeon assured the meeting that the hernias operated on by him never recurred. Langton thereupon rose to his feet, pulled out of his pocket a paper on which was written a list of the patients he had seen at the Truss Society with recurrent hernias and the names of the surgeons who had done the operations. "Your name, Sir," he said, "stands at the head of the list." The moral of the story, I fear, still holds good, for patients who have been disappointed in what they were led to expect was going to be "radical cure," tend to gravitate to the Truss Society rather than to return to the surgeon whom they regard as responsible for their disappointment. During the last ten years a record has been kept of patients with hernias that have recurred after operation; over 350 such patients have been seen, although this record is probably not quite complete.

Truss Society, 1917—1926.

Recurrent hernias:	
Inguinal	275
Femoral	90
	365

Clearly, therefore, there is still room for improvement in surgical technique. To some extent the result may perhaps be explained by the fact that there is a tendency for hernias to be operated upon at hospitals by the more junior operators, but I am sure that the blame can only be very partially shifted in this way. I believe that very few of the simpler cases of hernia dealt with by routine operations will show a recurrence. The failures are due rather to a lack of elasticity in the methods in general use, so that the more difficult technical problems are not always met by adequate adaptability on the part of the operator.

In the past, as the literature shows, an immense amount of ingenuity has been expended upon the details of ordinary operative procedure. I do not propose, however, to cloud the issue by dwelling on a great variety of methods of performing a routine operation for, say, congenital oblique inguinal hernia. I wish instead to direct attention to the comparatively few variations which I have introduced into my own practice for dealing successfully with the more difficult problems. I shall survey in succession the treatment of inguinal, femoral, umbilical, and ventral hernias.

INGUINAL HERNIA.

In operating on an ordinary oblique inguinal hernia I believe that the prime necessity is the complete removal of the sac, and that the other details of the operation are of small account. The difficulties will arise in treating direct inguinal hernias and oblique hernias in older patients whose muscles are atrophied and internal abdominal rings stretched. In the second type the conditions have approximated to the direct inguinal hernia, the deep epigastric vessels having been pushed towards the pubic spine. It is the close relation of the direct hernial sac to the pubic spine which is the chief cause of the difficulty in retaining the hernia by means of a truss. Patients with these hernias are often thin, and a truss-pad covering the whole area of the protrusion almost inevitably impinges on the pubic spine, and is thus rendered both inefficient and painful. Operation is therefore to be recommended for these patients, but if the routine operation for inguinal hernia is performed recurrence will almost certainly take place within a comparatively short time. The reason of this is not obscure, for the protrusion occurs in the triangle bounded by the deep epigastric vessels on the outer side, the edge of the conjoint tendon on the mesial side, and the pubic bone below. The transversalis fascia is bulged through this space and, even when the wide-mouthed sac has been ligatured and removed, it is impossible to suture the internal oblique muscle or the conjoint tendon to the inner part of the inguinal ligament in such a way as to form a strong floor to this part of the inguinal canal; for there is an actual deficiency in the floor of the inguinal canal which must be permanently closed (Fig. 1). A simple and satisfactory way of doing this is to use a flap derived from the internal oblique layer of the rectus sheath. The external oblique aponeurosis is lifted up, and can be separated from the internal oblique layer without difficulty. A semicircular flap is cut and turned over from above through 180 degrees so as to lie beneath the spermatic cord. The cut edge is then sutured with thick catgut to the inguinal ligament from the pubic spine outwards, almost to the internal abdominal ring. This flap then completely covers the site of the protrusion, and forms a new strong floor to the inguinal canal (Fig. 2). It is not under tension, and will therefore not tend to retract afterwards. The same procedure can be used for the smaller recurrent hernias and for others in which there is any doubt as to the efficacy of the ordinary operation. No additional shock or risk to the patient is thereby created. The results of this operation have been excellent, and no recurrence has yet taken place in a series of twenty-one hernias that I have dealt with in this way. The operation can be performed under a local anaesthetic with advantage both to patient and surgeon.

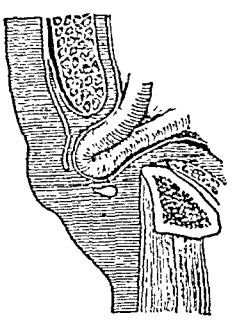

FIG. 1.—Diagrammatic section through the parts concerned in direct inguinal hernia, showing the two layers of the anterior rectus sheath.

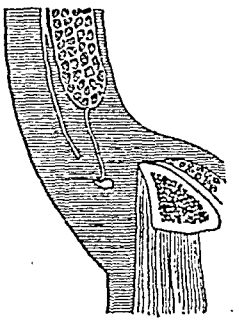

FIG. 2.—The same after removal of the sac, and suturing of a fascial flap to the inguinal ligament.

I shall now pass to the consideration of a much more serious problem—namely, the treatment of the large inguinal hernias in old and middle-aged patients, which until recently have been regarded by most surgeons with the greatest misgiving when the question of operation arose. The cause of these large hernias may be long neglect or the use of inefficient trusses. The patient may be very fat or very thin. At the best the hernia can be controlled by a large and perhaps irksome truss; at the worst it cannot be controlled at all by any truss, however ingenious. The hernia seems to slide out, round, over, or under any appliance that can be devised, and shows an almost devilish malignity in circumventing the efforts of surgeon and instrument-maker. If the patient is stout, the propulsive force exerted by his abdominal contents when he coughs or strains seems to be explosive, and in addition he is often engaged in a strenuous occupation, such as gardening or carrying quarters of meat in Smithfield Market. The final result will be that he becomes completely incapacitated, and the only appliance that can be used is that known as a "bag-truss"; this is not really a truss at all, but is, as its name implies, a bag designed to support the weight of the hernia, which would otherwise drag with its whole force on the skin of the scrotum, causing extreme discomfort to the patient. By the time that the bag truss stage is reached the operative prospects are, it must be admitted, wellnigh hopeless — not because the hernial aperture is too large, but because often the contents of the sac can no longer be accommodated within the abdominal cavity. Such a patient is likely to have been seen by more than one surgeon before he reaches this stage, but an operation has been thought to be likely to fail, and so he goes from bad to worse. I wish to insist that at the present time no patient should be allowed to reach this pass, since the hernia is now curable at an earlier stage.

Two years ago a most useful surgical tool was put into our hands by Professor Gallie of Toronto, and I believe that by its aid a cure can now be almost guaranteed to any patient suffering from even the largest hernia. The principle of Gallie's operation is not new in that it involves the use of a fascial transplant, but it is quite new in that the transplant is used in the form of a suture taken from the patient's own thigh. Gallie proved by experiments on animals that fascial sutures thus implanted are never absorbed, but *remain as healthy fascia* where they are put, so that a hernia treated by their aid remains cured. He had further successfully tested the method in a hundred human beings before he published it to the world. The operation is a major one and is by no means easy. Absolute asepsis is essential, and all skin surfaces must therefore be kept covered throughout th operation. The first stage is the incising of the stretche external oblique fascia and the isolation and removal of th hernial sac with all redundant tissues, so that the clea spermatic cord only remains. Meanwhile a second operato has incised the whole length of the opposite thigh, and he prepared three or four sutures each ten inches in lengt from the fascia lata. These sutures are threaded on larg curved needles specially adapted for the purpose. Th further stages can best be indicated by a series o diagrams.[1]

FIGS. 3, 4, AND 5.—GALLIE'S OPERATION FOR INGUINAL HERNIA.

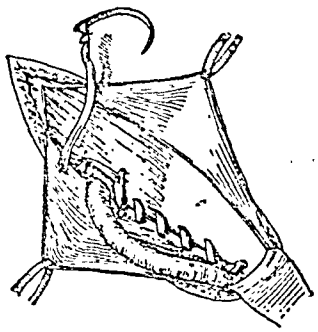

FIG. 3.—*Insertion of the first fascial suture and formation of a new internal abdominal ring.*

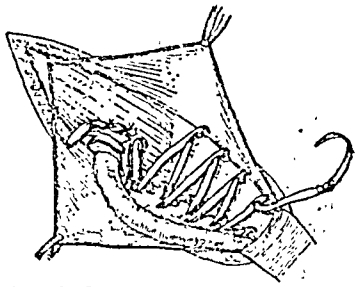

FIG. 4.—*Insertion of the second row of fascial sutures.*

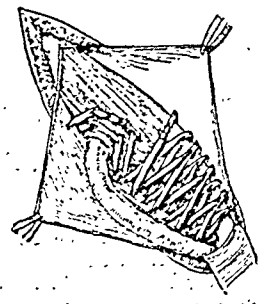

FIG. 5.—*Completion of the fascial sutures.*

1. The aponeurosis of the internal oblique is approximated to the inguinal ligament by a simple running suture which begins at the pubic spine and ends where the spermatic cord normally emerges from the abdomen; at this point it is locked by being passed through itself (*Fig. 3*).

2. A new internal abdominal ring is formed by a series of locked stitches passing from the inguinal ligament round the spermatic cord to the inguinal ligament on the outer side of the cord. A second row of similar stitches may be inserted in the opposite direction.

3. The first suture line is now oversewn by two or three layers of fascial stitches, passed zigzag fashion and self-locked at frequent intervals. These sutures are not under any tension, but are simply lying upon the first suture line so as to form a fascial grid which will in due course consolidate into a thick layer of tissue such as will effectually prevent any recurrence of the hernia (Figs. 4 and 5).

4. The spermatic cord is replaced upon the new floor to the inguinal canal thus formed, and the external oblique aponeurosis is sutured over it. This layer is probably thin and redundant, so that it must be overlapped by as much as is necessary to make all snug beneath it. This suturing can be done with a fascial strip if any remain over, but it is not essential, since the cure is not depending on this *suture line* for its permanence.

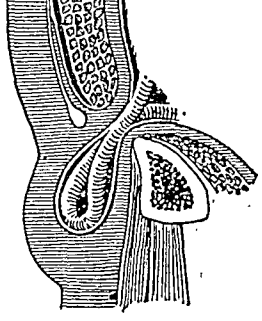

FIG. 6.—Diagrammatic section through the parts concerned in femoral hernia.

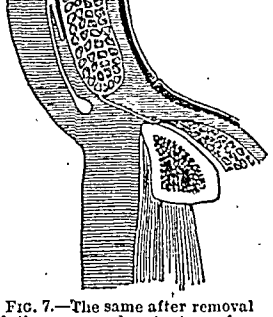

FIG. 7.—The same after removal of the sac, and suturing of a fascial flap to the ligament of Astley Cooper.

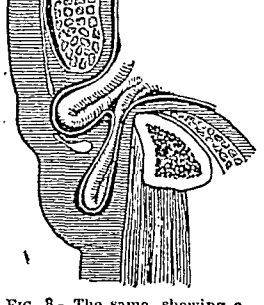

FIG. 8.—The same, showing a combination of direct inguinal with femoral hernia.

The patient must remain in bed for a fortnight, and at the end of this time he can be assured of possessing a very solid defence against future hernial protrusions, at any rate in the inguinal region. No attempt should be made to close the gap in the fascia lata, which does not

[1] For the very important smaller details of the operation the reader is referred to Gallie's original article, *Brit. Journ. Surg.*, 1924, xii, 283.

in any way incapacitate the patient afterwards. The whole operation will probably occupy from sixty to seventy-five minutes, so that a general anaesthetic will be contra-indicated for a stout and wheezy patient. The risk of bronchitis can be greatly reduced by the use of a local anaesthetic. My experience has shown me that the operation can be done more easily and cleanly with a local than with a general anaesthetic, and I should prefer to use it as a routine.

The results in the seven very large hernias for which I have used the operation during the last two years have been entirely satisfactory. One patient had two enormous direct hernias, the apertures of which would admit four fingers held flat. Gallie's method is, indeed, applicable to most of the worst hernias that are likely to be met with in ordinary practice.

FEMORAL HERNIA.

The treatment of femoral hernia is to me an even more interesting subject than inguinal hernia. Opinions are more sharply divided concerning it, while the general complacency as to the results appears to me to be even less justifiable than in the case of inguinal hernia. I hold strongly the view that femoral hernia should never be treated with a truss unless the patient refuses operation or is obviously unfit even for an operation with a local anaesthetic, and this is justified by the well known fact that the incidence of strangulation among femoral hernias is very much higher than it is among inguinal hernias. With this view most surgeons will agree, and in a large proportion of cases operation is performed. The rate of recurrence is, however, surprisingly high, and I find that during the last five years I have seen no fewer than 41 cases of recurrent hernia after operation among the comparatively small number of patients with femoral hernia attending the City of London Truss Society. This high rate is partly to be explained by the fact that the prevalent method of dealing with a strangulated femoral hernia leads almost inevitably to recurrence, and partly by the fact that the inguinal or "high operation" has not yet completely replaced the femoral or "low operation." The figures are as follows:

City of London Truss Society, 1921-1926.

Recurrence following "low operation"	27
Recurrence following strangulated hernia	14
	41

That is to say, one-third of the recurrences followed an operation for strangulated hernia; the remainder followed the orthodox "low operation."

Starting even from the morphological standpoint the problem of femoral hernia is a difficult one. In the case of inguinal hernia there is the clear-cut difference between the congenital and acquired varieties, and it is recognized that for the vast majority, since they are congenital, the removal of the sac is the basis of cure. But controversy still rages round the origin of femoral hernia. The congenital school, championed by Hamilton Russell of Melbourne, holds to the developmental origin during the growth of the limb bud, whereas Sir Arthur Keith leads the party which preaches that it is acquired. The discussion, though of great academic interest, is not, in my opinion, of much practical importance, as I am satisfied that, whichever theory be true, the mere removal of the sac is not curative. This point Professor Gask put to the test a few years ago. In 10 patients the hernia was treated by laparotomy with complete removal of the sac from within the peritoneal cavity. In 6 of the cases so treated the hernia promptly recurred, and this method of treatment had to be abandoned. The so-called "low operation" is also, in my opinion, unsatisfactory, and should no longer be used. In this operation a vertical incision is made in Scarpa's triangle (which usually results in a very ugly scar). The hernial sac is then isolated and ligatured as it emerges from the saphenous opening. Finally, the inguinal ligament is sutured to Cooper's ligament, or a purse-string suture

is used in an attempt to close the crural canal. The complete removal of the sac by this means is almost impossible for anatomical reasons; neither can it be supposed that an approximation of two tense structures, such as the inguinal ligament and the pectineal fascia, or the ligament of Astley Cooper, can be permanently maintained. That many patients treated by this method have been cured cannot be denied, for often the aperture through which the sac emerges is narrow, and a film of scar tissue is efficient in closing it; but as a routine procedure I believe it is theoretically unsound, and the recurrences that I have seen confirm this view in practice.

The inguinal operation is admittedly a more intricate proceeding, and demands an accurate knowledge of the anatomy of the parts concerned. The skin incision is made as for an inguinal hernia, which is an advantage to the patient, since it is in the line of cleavage of the skin and gives a very good scar, unlike the vertical incision used for the other operation. The lower flap of skin is raised and retracted, and the hernial sac is defined, isolated up to its neck, and opened. If it contains a large mass of omentum which cannot be reduced, this must be removed. The external oblique aponeurosis is then cleaned and incised as for inguinal hernia. The lower edge of the internal oblique is then retracted upwards with the spermatic cord or round ligament. The floor of the inguinal canal in its inner half is thus exposed and is incised. The opening is enlarged and, being on the inner side of the deep epigastric vessels, is immediately over the neck of the femoral sac above the inguinal ligament. The neck of the sac is seized, and the sac pulled up through the crural canal. Before being finally removed the sac must be carefully examined and any tissue on its inner side must be peeled away, for often this tissue is the lateral part of the fundus of the bladder. When the neck of the sac has been thus defined, it is ligatured flush with the parietal peritoneum and the sac is removed. Any operator who is unaware of this quite common relationship between the bladder and a femoral hernia is sure sooner or later to endanger a patient's life by including the bladder in his ligature. It now remains to deal with the opening of the crural canal. No attempt need be made to close this, for it is better to shut it off from the abdominal cavity by bringing down a curtain from above. This can be done in most cases by suturing the lower edge of the internal oblique with two or three mattress sutures to the strong extension of the lower horn of Gimbernat's ligament, known as the ligament of Astley Cooper. This procedure is open to objection in that a structure is again being dragged down out of its proper line of action into contact with another tense structure. In practice, however, it is found to be efficient when the opening of the crural canal is small. In most patients the lower edge of the internal oblique, being muscular, not aponeurotic, comes down without much tension. The muscle fibres no doubt undergo fibrosis afterwards, but the fibrous curtain so produced remains as an efficient bar against the recurrence of the hernia. The objection has been brought against the inguinal operation that it weakens the floor of the inguinal canal just in the position where a direct hernia is liable to develop. It is clear, however, that the internal oblique muscle, if used in the way described, is closing this deficiency in the floor of the inguinal canal at the same time that it is forming a curtain between the crural canal and the abdominal cavity.

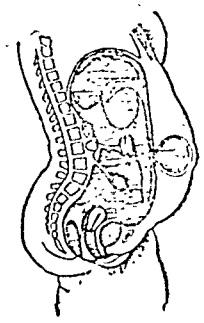

FIG. 12.—Diagrammatic section through an obese woman, showing the relation of the umbilical hernial sac to the surface.

This operation has been found to be efficient in 125 patients operated on by several surgeons in the wards of the Surgical Unit at St. Bartholomew's Hospital during the last six years. I was myself responsible for about a third of these. Most of the patients have been reviewed at intervals since they left hospital. In the great majority the crural canal was of the common small size, and I have found signs of recurrence in only three instances. I believe, however, that the operation described, though better than the low operation, is not to be relied upon where the opening is of larger size or where it has been deliberately enlarged as in dealing with a strangulated hernia. I have therefore devised another procedure for use in the more serious cases. The operation is probably not new, but I have been unable to find any description of it in the literature of the subject.

The principle involved is an extension of the plastic operation already described for the treatment of direct inguinal hernia. The earlier stages of the operation are carried out just as has been already detailed. But when the sac has been removed a rather large semicircular flap is cut from the aponeurosis of the internal oblique layer of the rectus sheath, and this is turned over through almost 270 degrees so that its lower edge can be sutured t the ligament of Astley Cooper or even to the periosteu of the pubic bone from behind Gimbernat's ligament t the femoral vessels (Figs. 6, 7, and 8). This stron aponeurotic curtain is under no tension at all, and remain as a permanent and efficient bar against recurrence of th hernia. Nor is any deficiency left in the floor of th inguinal canal. The suturing of this flap is not an ea thing to do. The sutures must be inserted at the botto of a deep hole, and the femoral vessels are in immine danger of being injured unless properly safeguarded. have found the operation is greatly facilitated by usir a wide retractor with a slit in the centre of the blad The instrument is so inserted that it retracts and protec the femoral vessels both above and below the ingui

FIGS. 13, 14, AND 15.—OPERATION FOR UMBILICAL HERNIA.

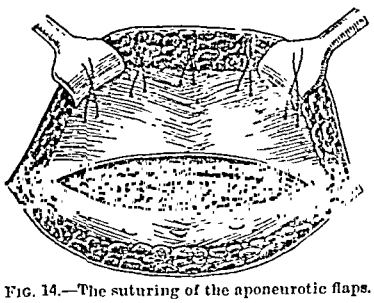

FIG. 14.—The suturing of the aponeurotic flaps.

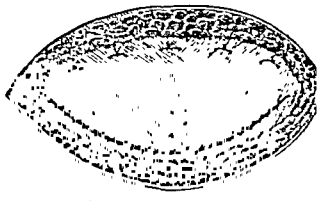

FIG. 15.—The operation completed with tw rows of sutures.

ligament, which is itself occupying the slit in the centr Adequate room for working is thus obtained, and th retraction of the vessels outwards ensures that they con closely up against the outer edge of the aponeurotic fl when they are released. When the sutures are being i serted the needle carrying them must be made to emer below the crural canal and is then passed back aga through the canal, so that the sutures are tied above th inguinal ligament. Three deep sutures are usually enough a fourth is sometimes inserted to secure the outer edg of the flap to the inguinal ligament over the femor

vessels (see drawings). The external oblique aponeurosis is then sutured as before. The stages of the operation are shown in the accompanying drawings (Figs. 9, 10, 11).

This operation I have now performed twenty-one times:

Reasons for which the Operation was done.

Large hernia	11
Recurrent hernia	4
Strangulated hernia	3
Prevascular hernia	1
Bilocular hernia (Fig. 8)	1
For demonstration	1
	21

It will be seen that in all except one case the circumstances made the routine operation unlikely to result in a permanent cure. In every patient so far treated in this way the result has been satisfactory. Several patients have been men doing heavy work. I make no apology for having done the operation on one occasion in order to demonstrate it to another surgeon, for I believe it to be theoretically the best operation for all cases; it takes, however, a somewhat longer time to perform than the other operation, and it seems unnecessary to use the more elaborate method when the simpler suffices.

One of the most important applications of the inguinal operation, and of my own modification of it in particular, I believe to be in the treatment of strangulated femoral hernia. The low operation may be actually dangerous, and should seldom be used. It is well known that a common form of strangulated hernia is the so-called "Richter's hernia," in which less than the whole circumference of the intestine is nipped in the neck of the sac. Sometimes the sharp edge of Gimbernat's ligament causes a local necrosis of the wall of the gut where it is in contact with it, so that perforation is liable to occur. If any attempt is made to deal with the hernia from below, the manipulation may only result in the premature reduction of the contents. The perforated gut slips back into the peritoneal cavity, and the patient is likely to die of general peritonitis. Even if this does not occur, it will be difficult to deal satisfactorily with the strangulated gut from below unless the crural canal is first greatly enlarged. Often this has been done in the past by dividing Gimbernat's ligament, and I believe it is the destruction of this important structure which has contributed largely to the very high rate of recurrence following the relief of a strangulated femoral hernia, as illustrated by the figures already given. I believe, therefore, that the high operation should always be used when the hernia is strangulated, and that it is usually more important to do the operation properly than to save time. The peritoneal cavity must be opened above the inguinal ligament before the hernial sac is opened, and the loop of gut entering the hernia must be identified. The surgeon then has complete control of the situation, and the patient is protected against the danger mentioned above. The sac is then opened, and the constriction at the neck is relieved, not by dividing Gimbernat's ligament, but by nicking the anterior margin. In this way only the fibrous tissue in the neck of the sac is incised, or at the worst some fibres of the inguinal ligament. The strangulated gut can thus be reduced, and is treated appropriately according to the condition found. The sac is then removed and the peritoneum closed. It now remains to finish the operation in such a way that the hernia will not recur. Gimbernat's ligament has not been damaged, but the opening is likely to be fairly large after the hernia has been reduced. Recurrence can be prevented by turning down a flap from the rectus sheath, as already described, the operation being done with the same care as would be used in doing it under ordinary conditions.

I have insisted that the time factor is not necessarily of great importance because I have found that the operation can best be done under a local anaesthetic. The patient suffers very little disturbance by this method, and there is no necessity for haste. I have done the operation in this way on a frail old lady of over 80, who made an uninterrupted recovery, and it has been equally satisfactory in other patients. The last one that I operated on had a hernial sac measuring 5 by 3 inches and containing a large mass of omentum with several inches of strangulated gut; size, however, is no bar to the successful employment of local anaesthesia, and this patient was undisturbed by the operation, and made an uneventful recovery.

Umbilical Hernia.

Umbilical hernia as seen in children does not often call for operation, and when it does so a cure can usually be effected without difficulty, whatever form of operation is used. The case is very different, however, with the other common type—namely, the obese woman with a large umbilical hernia—and the problem of treating such patients is a very difficult one. The hernia is usually protruding into a sac which is larger than it appears to be on the surface, owing to the fact that it is obscured by a layer of fat several inches in thickness (Fig. 12). Sometimes it is possible to make the patient comparatively comfortable by applying a truss or a combination of abdominal belt and truss, but it is obvious from the anatomical nature of the case that the control of the hernia can never be more than partial. The risk of strangulation always remains a grave one, and it is well known that when this occurs the patient's life is in great danger. The lot of an obese woman with a hernia is, indeed, an unenviable one, and I feel that we do not perhaps do quite as much as we might to alleviate her discomfort. Her lungs usually show emphysema and chronic bronchitis; her heart muscle is likely to be infiltrated with fat. Her figure, with its immense capacity for propulsion of abdominal contents through any weak point in its armour, seems to offer little chance of a permanent cure of the hernia. Nevertheless, I believe that we tend to take too gloomy a view of the prospects of operation, and the source from which the ray of hope emanates is a flaskful of novocain-saline-adrenaline solution.

I have found the radical cure of umbilical hernia under local anaesthesia to be a practicable undertaking even in the most obese of patients, and the post-operative terrors of vomiting, coughing, and heart failure are thereby largely removed. It is, of course, difficult to make sure of doing an efficient infiltration of all the layers by injection through the skin, but a preliminary superficial infiltration, followed

FIGS. 16, 17, AND 18.—GALLIE'S OPERATION FOR VENTRAL HERNIA.

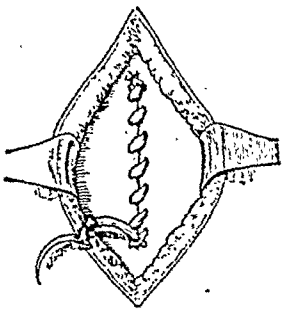

FIG. 16.—Insertion of the first fascial suture.

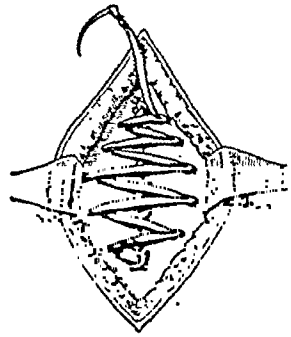

FIG. 17.—Insertion of the second fascial suture.

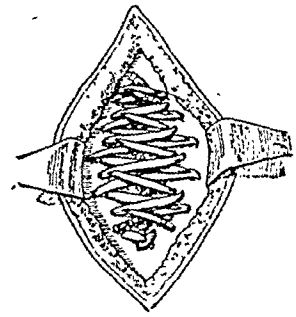

FIG. 18.—Completion of the fascial filigree.

by an infiltration of the deeper layers after the skin incision has been made, will give complete anaesthesia of the parts concerned. The details of the operation have been the subject of controversy. Some surgeons advocate a longitudinal incision encircling the stalk of the hernial sac, removal of which is followed by suture of the aponeurosis of the linea alba, which is always greatly widened in these patients and can be overlapped from side to side. My own feeling is in favour of the other method advocated by the surgeons of the Mayo Clinic, their observations being based upon the results obtained in a large number of patients. The incision in this operation is transverse in both skin and aponeurotic layers. When the skin has been incised the hernial sac is defined and isolated, and the surface of the aponeurosis is cleared of fat for some distance around it, especially at the sides. An incision is then made through aponeurosis and peritoneum close to the neck of the sac, and this is carried right round the neck so that the sac, with its contents, is separated from the abdominal wall (Fig. 13). The sac is then opened and its contents either cut away or replaced in the abdomen as seems best; afterwards the peritoneum is sutured. The incision in the aponeurosis is next extended to either side as far as, or even into, the sheaths of the widely separated rectus muscles. Material can thus be obtained for overlapping the aponeurosis from above and below the situation of the former hernia, and this double layer should, in theory, form an effective bar to the recurrence of the hernia. The edge of each layer of aponeurosis is separately sutured to the other so that the strain of any coughing or vomiting after the operation is borne by a double row of sutures (Figs. 14, 15). Cure must finally depend, however, upon a firm adhesion between the surfaces of the overlapping layers of aponeurosis, since the sutures of catgut or kangaroo tendon which are commonly employed are but a temporary means to the end in view.

I have recently reviewed the patients who have been operated upon for umbilical hernia in the wards of the Surgical Unit at St. Bartholomew's Hospital. The numbers are not large enough for them to form the basis for definite conclusions, but the results at any rate show that there is at present no ground for complacency, for among ten patients operated upon by the transverse method, recurrence has taken place in three within a period of five years. The chief grounds advanced by the surgeons of the Mayo Clinic in favour of the transverse operation were the mechanical conditions governing the tension of the abdominal wall. The recti are widely separated and acting weakly, so that when the abdominal muscles contract the obliques are the strongest agents and will tend to pull open a longitudinal scar, but to close a transverse one. But after having performed the operation by their method with great care on a number of patients and having found a recurrence taking place in a patient in whom everything seemed favourable and an entirely satisfactory result had been expected, I have come to the conclusion that there is still need for improvement in some part of the treatment. The advantages of using a local anaesthetic I have already mentioned. The weak point in the technique to which I am inclined to attribute the chief responsibility for the failures is the use of dead materials for suturing the aponeurosis. Evidently these sometimes retain their hold on the tissues long enough for adhesion between the layers to take place; but sometimes they do not, and I believe that if fascial sutures are used for this purpose a cure is likely to be obtained with much greater certainty. It is clearly another department in the treatment of hernia in which the principle of Gallie's operation ought to be employed.

POST-OPERATIVE HERNIA.

It only remains to deal with the miscellaneous hernias which are so liable to follow emergency abdominal operations of all kinds, and sometimes follow operations that were not to be classed as emergencies. Most of the former are unavoidable, most of the latter avoidable; the present discussion, however, is concerned only with their treatment when they have appeared. Those that are met most commonly in practice are in the right iliac fossa after drainage of an appendix abscess, or in the epigastrium after an operation for a perforated ulcer. Others are in the mid-line above the pubes following a prostatectomy. Another type, common in my experience at the Truss Society, is found in obese middle-aged women following a gynaecological operation, and occupies the greater part of the mid-line between the umbilicus and the pubes.

Many of these post-operative hernias can be more or less controlled with some form of truss, though operation is always to be preferred unless the patient's physical condition renders him unsuitable for it. Unfortunately, many patients have suffered enough under the first operation to make them reluctant to undergo a second. They are naturally unable to appreciate the fact that the repairing operation can usually be performed under a local anaesthetic with comparatively little pain or discomfort. The surgeons to the Truss Society have consequently had to devise many forms of truss for these hernias, which, however, I should prefer not to discuss under the title given to this paper, for the *modern* treatment of the condition can, I believe, offer an almost certain cure. In most instances, as I have said, a local anaesthetic can be used with advantage. For many of the interstitial hernias following operations for appendicitis a technique suffices, which aims at excising all scar tissue with careful suturing, of each layer in turn after it has been cleaned and defined. The case is different with the ventral hernias, especially those of the suprapubic variety, for it is difficult to find undamaged tissues for accurate suture, and recurrence has frequently followed the most painstaking attempts. The application of Gallie's principle is again found to be the solution of the difficulty, the procedure being similar to that already described for inguinal hernia, though somewhat simpler. The more difficult part of the operation is likely to be the preliminary stage—namely, the removal of the sac, followed by replacement of the contents in the abdominal cavity and suturing of the peritoneum. When this has been done the other anatomical layers used need not be defined. Even the thicker parts of the scar tissue at the edges of the opening may be used. These edges are approximated with a simple running fascial strip suture, which is locked at either end (Fig. 16). The first suture is then oversewn with at least two layers of zigzag stitches, frequently self-locked, exactly as already described for dealing with the aperture of inguinal hernias (Figs. 17, 18). If the hernia is immediately suprapubic, the first suture at any rate must begin at its lower end deep to the pubic bone itself, so that not the smallest protrusion can possibly occur afterwards at this point. Gallie's technique is so satisfactory for the repair of these hernias that it should be used without hesitation whenever there is any uncertainty as to the success of a less drastic method.

CONCLUSION.

I wish to make somewhat high claims for treatment carried out on the lines I have indicated, for I believe that by their means success can now be assured even in those cases in which formerly the results were most in doubt. The main points that I have tried to make are:

(1) The great value of a local anaesthetic in making the operation easier for the surgeon and less dangerous for the patient, with elimination of most of the accidents likely to influence adversely the prospects of permanent cure. The risk of toxic effects on the patient, even in so extensive an operation as Gallie's method, is *nil*, since a solution of novocain 0.2 per cent. in normal saline solution with adrenaline 1 in 200,000 is all that need be used.

(2) The uses to which a fascial graft of the patient's own tissue may be put, the graft being derived from the actual operation area. In this connexion I have described an operation for femoral hernia which may be new and has proved satisfactory in a considerable number of cases.

(3) The very great advance which has resulted from the addition of Professor Gallie's technique to the surgeon's operative repertory. This again involves the use of the patient's own tissues, though the graft is taken from a distance and employed in the form of a living suture.

I am aware that even more extensive plastic operations have been described in the past, but these I regard as applicable only to such exceptional circumstances that they do not come within the scope of this survey. I am also aware that some surgeons still advocate the use of foreign materials such as silver filigrees for inguinal hernias and iron staples for femoral hernias; but although these methods may give excellent results in some hands, I believe that they are contrary to the general trend of modern surgery, which prefers to discard such artificial aids when cure can be obtained without the introduction of any foreign materials.

ACUTE INTESTINAL OBSTRUCTION DUE TO INTRA-ABDOMINAL CAUSES.

BY

SIR HENRY GRAY, K.B.E., C.B., C.M., F.R.C.S.ED.,

MONTREAL.

IN the earlier years of my surgical experience there was a very decided prejudice against the employment of surgical measures in the treatment of acute intestinal obstruction. This prejudice was, in a measure, not to be wondered at, because the results of surgical intervention at that time, when surgery was a "last resort," were extremely depressing.

In those days, judging from my experience in Scotland, there were, relative to the number of operations performed, a good many more cases of acute intestinal obstruction compared with the number encountered in more recent years. A considerable proportion of cases occurred as a sequel to abdominal operations. That number was greatly reduced owing, I think, to more rational and careful methods of conducting such operations and their after-treatment. For example, one important item in preventing adhesions and band formation is strict attention to the exclusion of raw surfaces by "peritonealization" of pedicles and careful suturing of the abdominal wall. The irritation of rubber tubes and other stiff material used as intra-abdominal drains stimulates adhesions, from the formation of fibrous tissue, and predisposes to obstruction from kinks or bands. I have for many years almost entirely given up the use of such intra-abdominal drains as a routine, except after operations on the biliary passages, liver, or pancreas.

All cases of intestinal obstruction are urgent—some more so than others. This urgency is dependent on the age and general condition of the patient, on the actual cause of the obstruction, and on its site. Very young and very old individuals, or patients enfeebled by concomitant disease of vital organs, are likely to go under rapidly. They cannot endure the intense pain, and may quickly succumb to shock. If pain is not typically severe in such a case the attendant may be tempted to procrastinate, but it must be remembered that the effects of toxaemia are apt to be more intense and rapid in them and to be less easily combated than in more robust individuals.

The effects on the bowel itself vary greatly according to the cause. Slight constriction or simple kinking may at first merely prevent passage of intestinal contents. Later on, increased pressure of these contents, and the congestion due to the thin-walled veins being more readily occluded than the arteries, may ultimately bring about exactly the same state of affairs in this primarily simple occlusion as in the more dangerous condition of strangulation, whether caused by band, volvulus, or intussusception. The degree of interference with the circulation of the bowel, with the nerve supply, with the mucous membrane, and the lymphatics, and with the walls of the gut as a whole, influences the rapidity with which symptoms appear and their severity.

A tight snare caused by a band over or around the bowel may affect the whole of its constituents so much, from the onset, that gangrene will occur rapidly, and be followed by peritonitis. In some cases the snare may merely be tight enough to cause, at first, occlusion only of the veins of the bowel, but this brings on congestion and distension, so that the snare gradually becomes tighter, with involvement of other structures and corresponding increase in the severity of all the symptoms. The ultimate result of embolism or thrombosis in the mesenteric vessels is practically identical.

Apart from the purely mechanical factor in acute intestinal obstruction, there is another and almost equally important one—the absorption of toxic material from the bowel. This material is derived either from bacterial decomposition of the bowel contents above the obstruction, or from imperfect metabolism of protein contents (producing proteoses), which may have been swallowed, but more likely are secreted or exuded directly into the bowel through its mucous membrane. Toxins of the second class are more dangerous and rapid in their action. Their effect is best seen in obstruction high up in the small bowel, where bacterial decomposition is not prominent. The jejunum has been called the "poisonous proteose level" in obstruction. In these cases toxaemia becomes evident very soon, producing definite prostration or symptoms of actual shock. Persistent vomiting is established at an early stage, and is probably dependent as much on the toxaemia as on mechanical causes. Both symptoms pass off just as quickly as they appeared, after the contents of the bowel are drained away through an enterostomy. The origin of these toxins, however, is still a matter of debate. Apparently the presence of bacteria is necessary before they can provoke a fatal issue. Vomiting and toxaemia may be long postponed when the obstruction is low down in the bowel. A third important factor is the rapid depletion of the body fluid as a whole and of some of its constituents in particular. This has often a marked effect on the general circulation. In some cases the sunken eyes, pallid or "blae" facies and hands, and shrunken limbs are striking features. But these are symptoms of advanced cases of obstruction, which, in ordinary circumstances, at least of town practice, should not be allowed to occur.

ETIOLOGY AND PATHOLOGY.

In infants and young children intussusception is by far the most frequent condition which produces obstruction of the bowels. Improper feeding, causing inco-ordinate and excessive peristalsis, as well as swelling of the lymphoid accumulations which are prominent anatomical features in the wall of the bowel at this time of life, are probably the most frequent causes of this. During ordinary peristalsis, as opposed to segmentation, a distal part of the intestine dilates while the part immediately proximal to this contracts and forces the bowel contents onwards. If the contraction is excessive, the contracted part may be forced into the dilated part, which, in turn contracting, tends to carry this apex of the intussusception still further. This is apt to occur more easily in a child, in whom the equilibrium, so to speak, of the bowel is not so highly developed as in an adult, and these lymphoid swellings are apt to be caught and forced onward by the peristaltic wave. As the process develops, the bowel becomes more and more infolded, causing congestion, swelling, occlusion of the gut and its vessels, and traction on nerves, with attendant haemorrhage and shock. In early stages the symptoms may abate because the intussusception may recede. But later on it remains strangulated and will speedily become gangrenous. In such cases the symptoms are severe and persistent, until their severity is masked by the exhaustion of the bowel and of the patient.

Children with complete obliteration or high-grade stenosis of a segment of bowel are often in such poor condition that surgical intervention is out of the question. If, however, there is no doubt of an obstruction, as revealed by persistent vomiting, local distension, and possibly by x-ray evidence, it may be worth while to give an otherwise healthy child its only chance. A rapid short-circuiting operation is usually the best procedure. Obstruction at this age may be due to a diaphragmatic hernia or to strangulation through a hole in the mesentery.

Intussusception in older children and adults is usually due to some accompanying pathological condition, most frequently a polypus, and more rarely a stricture. Intussusception or, as it is more often called, prolapse of the sigmoid or rectum, may occur without such accompaniment, and may be predisposed to by a curious ballooning of this

part of the bowel which occurs in some cases and which is not satisfactorily explained. The ballooned condition may have a distant relationship with the equally unexplained condition called Hirschsprung's disease—an idiopathic and apparently congenital condition of the large bowel, in which the lower part is most severely and most frequently affected.

Intussusception in adults is, however, comparatively rare. At this age the most usual causes of intestinal obstruction are fibrous bands, internal hernia, Meckel's diverticulum, volvulus, impaction of concretions, sudden blockage of a chronic stenosis brought on by tubercle or cancer, or pressure from a tumour outside the bowel, and chronic or recent adhesions causing acute angulation of the bowel. The last is usually the cause of obstruction accompanying acute peritonitis from appendicitis or salpingitis, or after an abdominal operation. In inflammatory cases the symptoms of obstruction may mask those of the cause; the case usually becomes much more urgent when obstruction supervenes.

In all these cases there need not be at first any actual microbial inflammation of the bowel wall, so that, with careful coaxing, the bowel usually recovers, after being released. I should like to point out, however, that strong purgative medicines given by the mouth, and endocrine or other selective remedies, such as pituitrin and eserine, administered subcutaneously, sometimes defeat the object with which they are given. Immediately after operation the bowel may not be in a condition to respond to drastic stimulus. The so-called adynamic or paralytic ileus may possibly occur after any abdominal operation, but especially if the bowel has required much handling, and where over-distension has existed previous to operation.

The most frequent and serious form of paralytic ileus is that caused by peritonitis affecting the lower half of the abdomen, which is occupied by both small and large intestine, both of which become affected by the peritonitis—hence Sampson Handley's term "ileus duplex." This term indicates that both large and small bowel are affected and must be treated, in my opinion by caecostomy and jejunostomy; Sampson Handley recommends a jejuno-colostomy. In such cases stagnation occurs in the distended, sodden, flabby loops of intestine, and the poisonous contents of the bowel, acting on the intestinal wall, tend to keep up the paralytic condition. Unless the vicious circle can be broken, either by emptying the bowel above the obstruction as much as possible at operation, or, better, by making one or more openings in the bowel through which its contents gradually drain away, the patient will die.

With reference to the acute toxaemia which occurs especially when the obstruction is situated high in the small intestine, it appears that the poisons absorbed from the upper jejunum, and especially from the duodenum, exert profound metabolic changes, which can be easily appreciated in the blood, and are evidenced by great diminution in the chloride content, increase in blood urea, and in the capacity of the blood for carrying CO_2. Such changes are early appreciable in paralytic ileus. In the later stages this toxaemia exerts an evil effect upon the kidneys. These organs often undergo acute inflammation, which shows as changes in the tubular epithelium or as a more diffuse nephritis. The urine may contain granular and hyaline casts, albumin, and even occasional red blood cells. It usually becomes normal again rapidly when the obstruction is relieved and the fluid deficiency of the blood is made up. These changes in the blood, especially the deficiency in chlorides, give valuable indication for treatment. The chloride deficiency can be remedied by giving ordinary or hypertonic solution intravenously. J. W. Ross of Toronto[1] has suggested the use of intravenous infusion of hypertonic saline solution (60 to 75 c.cm. of 20 per cent. sodium chloride for an average adult). This suggestion was based on the observation of Hughson and Scarff[2] that violent peristalsis immediately followed the injection of this solution and persisted for an hour. With more dilute solutions there was a latent period and less active response. They found also that absorption of toxic products from the gut was delayed. Thus the administration of hypertonic saline has three beneficial effects: (*a*) replenishment of depleted chlorides, (*b*) retardation of absorption of toxic bowel contents, and (*c*) stimulation of active peristalsis. After the hypertonic solution has produced peristalsis, ordinary isotonic solutions may be required to replace lost body fluid.

SYMPTOMATOLOGY.

As has already been indicated, the clinical symptoms of obstruction may vary considerably, chiefly according to the site and the cause of the obstruction. At the same time there are certain phenomena which are almost invariably found, forming quite a characteristic symptom-complex. Over a period of days or even of weeks the patient may be subject to occasional recurring colicky pains, generally in the same part of the abdomen. These pains may gradually or suddenly increase in severity with development of the typical syndrome. Such patients are usually the subjects of adhesions or of growth.

The symptoms, however, usually appear with dramatic rapidity. If a loop of the bowel suddenly becomes acutely strangled, severe local irritation and pain are caused, resulting in variable manifestations of shock or, as it is called by some, peritonism. The patient may become more or less collapsed, with feeble pulse, clammy skin, drawn features, and intense pain in the abdomen. He may vomit owing to the shock, and the lower bowel may respond to the irritation by evacuating its contents. After this preliminary storm may come a more or less pronounced calm, although there may persist considerable steady pain in the abdomen, usually referred to the umbilical region when the small intestine is the seat of trouble, and to the hypogastric region when the large bowel is affected. In some cases the respite may be so definite that the patient drops off to sleep. Very soon, however, the pain becomes more intense, and is accompanied by spasms of colic, which become so severe that the patient writhes in agony. These spasms occur more frequently and are more intense when the small intestine is affected. When the large bowel is blocked the spasms are bad, but, while they may make the patient sweat with pain, he does not usually cry out as does the sufferer from colic of the small intestine.

Persistent vomiting soon sets in. At first any food remaining in the stomach is evacuated, then bilious material, then more or less clear watery material as the contents of the small intestine regurgitate into the stomach, and finally, as congestion and decomposition increase, the vomit becomes brownish—it is often described as being faeculent in character. At this stage vomiting is frequently "forcible," "pump-like," strikingly different from the overflow, in mouthfuls, which characterizes the act when peritonitis and paralysis of the bowel are present and cause steady regurgitated accumulation in the stomach. When the latter type of vomiting threatens there is urgent need for *high enterostomy—one or several*. The higher the situation of the obstruction in the small intestine, the more severe usually is the persistent pain, the more frequent is the colic, and the earlier is the onset of vomiting. The patient is usually earlier and more profoundly collapsed—the combined result of toxaemia and implication of the superior mesenteric plexus.

If the strangulation or volvulus of any part of the bowel is severe, the congestion and distension of the affected coils may be so great that the resultant persistent pain may almost overshadow the colicky pain which is caused by peristalsis of the bowel above the strangulation. In such cases localized bulging of the abdomen, accompanied by the sensation of a tumour mass on palpation (which used to be called von Wahl's symptom), may develop quite early, and before general distension occurs. This tumour is felt more easily during expiration and under anaesthesia.

The tumour mass, often sausage-shaped, which is frequently felt in cases of intussusception, varies in bulk and position according to the presence or absence of colic and spasm. During a spasm the mass becomes larger and progresses towards the rectum. In the intervals between spasms the mass may be followed with the fingers towards the iliac fossa, the tumour decreasing in size. Frequently it cannot be palpated, but absence of tumour should not interfere with diagnosis; presence of tumour merely confirms it. I have only once felt the apex of an intussus-

ception per rectum. Dance's sign is merely the appreciation of a vacuity in the right iliac fossa from which the caecum, etc., has taken flight.

Pressure with the flat of the hand, though stated to relieve the pain, does not do so, but often aggravates it, especially when a coil is strangulated. A succussion splash in the distended coils above the point of strangulation may be elicited in the intervals between spasms of colic, and may point to the site of the obstruction; this is also sometimes indicated by an area of great tenderness in the abdomen.

While general distension of the abdomen occurs fairly rapidly if the lower part of the small intestine is affected, it may not occur in strangulation of the upper part; the stomach alone may cause localized bulging. Distension is said to occur much later in obstruction of the lower part of the colon or in the rectum. It is suggested that when the small intestine is irritated and blocked, a considerable exudation of fluid occurs into the lumen of the bowel, which is not sufficiently rapidly absorbed, but that when the lower colon is blocked the upper part still goes on absorbing fluid fairly well. This explanation is not quite satisfying. In the large intestine gas-producing bacteria are ordinarily far more numerous than in the small bowel, and the former is, therefore, more tolerant of decomposition than is the small intestine, in which irritation, congestion, and distension are more likely to produce increased and abnormal secretion and inflammatory exudate, which, with the half-digested food material, promote decomposition and gas formation. Owing to congestion of the obstructed loops free fluid may accumulate in the peritoneal cavity, and may even be sanguinolent. In later stages its serous character may be lost owing to the onset of peritonitis.

Obstruction in the small intestine has been shown to render the bowel more permeable, so that imperfectly digested proteins, etc., gain entrance to the blood; this may explain the excessive amount of urea in the blood. This excess disappears at once when the obstruction is relieved and the bowel has resumed its function.

Constipation is a very prominent feature and should always be impressive, because when colic occurs without obstruction it is always accompanied, sooner or later, by the passage of gas or faeces. But here, after the bowel has become emptied of contents below the site of obstruction, constipation becomes absolute, usually neither flatus nor faeces being passed. Since ordinary colic is the result of indigestion, purgatives or enemata are often administered in an attempt to cure constipation when it is present. In cases of obstruction purgatives increase the colic and may bring on more violent vomiting. Because the bowel below the obstruction may have been more or less loaded with faeces, the first or even a second enema may have what is called a good result. But the giving of an enema will not relieve the pain and colic, unless in some rare cases of intussusception or kinking of the bowel where reduction takes place. Further enemata are unproductive. Thus there should not be great difficulty in diagnosis when the pains continue unabated or even exaggerated. The result of the first enema may be disregarded, but if subsequent enemata are followed by the passage of flatus or faeces the probability is against complete intestinal obstruction. If such obstruction is present, constipation is usually absolute after the first enema has evacuated the lower bowel; this fact is a most valuable aid in early decision about the case.

If the obstruction is not relieved the muscular coats of the bowel become exhausted, and on that account pain may be relieved to some extent. At this stage the nervous mechanism of the bowel is liable to become poisoned by toxins manufactured in the stagnating contents ("splanchnic intoxication"); this may result in paralysis or at least paresis of the bowel. Sooner or later organisms penetrate the walls of the bowel at or above the obstruction, add to the paresis, and cause peritonitis. A circumscribed patch of gangrene may occur owing to the pressure of the obstructing band on the outer wall of the bowel. Ulceration, commencing in the mucous coat, may result from the excessive stretching and consequent ischaemia, or one or more loops whose circulation has become obstructed, whether by band or twist, may become necrotic *en masse*. Perforation may occur through the gangrenous area.

The picture presented by the patient at this time is a very miserable one. Some describe it as a condition of secondary shock. In large part the symptoms are due to more or less profound toxaemia and to loss of fluid, from persistent vomiting and sweating. The face is drawn and pale, often dusky, the eyes are sunken, the skin is cold with clammy sweat. The nose, ears, and fingers may be mottled and blue, with stagnating capillary circulation. The pulse is feeble, thready, rapid; respiration is rapid, often sighing, and the temperature is probably subnormal. There is persistent, insatiable thirst. There is only occasional colicky pain. Vomiting becomes of an overflow character. The patient may be unusually alert mentally; he often does not realize the seriousness of his condition, and the end may come rapidly.

Allowing for individual idiosynerasies, there is no doubt that the amount of pain in intestinal obstruction varies considerably even while the pathological conditions are very serious. Stenosis and congestion may vary very widely, as may the clinical symptoms. Although usually the intensity of the symptoms is an indication of the severity of the pathological developments, yet sometimes there is no such correlation. Symptoms may be severe while the cause and pathological results are comparatively insignificant, and vice versa.

The chemical condition of the blood, the permeability of the blood vessels and of the mucous membrane, may be such that bleeding results very readily when the bowel is squeezed and becomes congested. One may find a strangulated loop of intestine full of clotted blood. I well remember a case of intussusception in which by far the most prominent symptom was severe haemorrhage from the bowel. The griping pains were so slight that the medical attendant could hardly decide upon invoking surgical aid, yet a well developed ileo-colic intussusception was found. Although the haemorrhage had been profuse, the intussusception was reduced with extraordinary ease. Comparable conditions are seen when, from the straining and consequent congestion caused by vomiting or difficult defaecation, bleeding either from the nose or from the bowel occurs—sometimes quite profusely.

Lulls in the storm of obstructive symptoms occasionally occur and may be so decided that the patient and his friends may refuse to allow operation, however clear the diagnosis may be.

There is usually so great urgency in most of these cases that it is dangerous to wait for the results of special laboratory examinations, even though the urine and blood may give most valuable indications for both operative and post-operative treatment. The questions, whether blood urea is present in large excess, and whether chlorides have largely disappeared from the blood, ought not to influence the operative procedure. It is possible to decide, from the urgency of the vomiting and appearance of the vomitus, and, at operation, from the state of the bowel proximal to the obstruction, whether these constituents are likely to be found in abnormal quantities in the blood, and much more certainly it can be decided whether that part of the bowel is likely to recover its tone or not before the patient dies. Over-distended but still contracting bowel is likely to recover; over-distended but inert bowel, incapable of response to external stimulus such as pinching, will almost certainly not recover if left to itself. Before the latter condition has developed, gangrene of the strangulated part will probably have occurred. The only chance for the patient in such cases is either to excise the gangrenous part and flaccid bowel above, as Arthur Barker advised, or to make a smaller excision and then perform enterostomy, single or multiple, in the bowel higher up. The procedure I want to emphasize especially is enterostomy, through which opening the poisonous contents of the upper bowel are drained away.

TREATMENT.

Sir Berkeley Moynihan, in his book *Abdominal Surgery*, says that of any twenty consecutive cases of average intensity in fifteen operation has been too long deferred.

Again, "To operate early in a case of intestinal obstruction is an experience that few surgeons often enjoy." The mortality after operation in these cases is far higher than it might be. There are "few surgeons who, in a series of twenty or more cases, can show a lower mortality than 50 per cent. Anything over a 10 per cent. mortality is the mortality of delay." Serious consideration of the symptoms which I have detailed ought to establish the diagnosis within a few hours.

The use of morphine or other sedative is frequently a bar to early diagnosis, because it is often used without good judgement, though it is often necessary to give morphine when the patient is seen for the first time, on account of the excruciating pain and impending shock. But, as Moynihan says, avoid needless repetition of morphine; this does the harm. If a small dose of morphine fails to relieve the recurrent colicky pains, apprehension should arise that early operation may be required. There is no absolute necessity to give morphine, and still less is there justification to repeat the doses until diagnosis is established. When that is done, then, as Moynihan remarks, "*morphine is a remedy and not merely a refuge.*"

There are certain necessary procedures which are necessary to operation and which become increasingly important as the condition develops in intensity.

First, it is necessary, if the patient has been vomiting at all, to wash out the stomach thoroughly, especially before giving a general anaesthetic, otherwise he runs the risk of being drowned by his own vomit or of inhaling vomited material and bringing on septic pneumonia. Spinal or even local anaesthesia does not entirely obviate these risks.

Many years ago I was called to a remote village, to find the patient, a large, heavy man, in a very pitiable and distressed state owing to neglected chronic obstruction which had suddenly become acute. I thought that while he would not stand a general anaesthetic, he would be able to control his vomiting, so that it would not choke him, if we gave him a spinal anaesthetic. I wanted to avoid for him the further distress of having his stomach washed out, since he was very nervous and had a bad heart. I neglected to tell him that his legs might become paralysed temporarily. When the spinal anaesthetic took effect, he suddenly realized that he could not move his legs. He took fright, became greatly excited, fainted, vomited profusely, and was really drowned by his own vomit, although his enfeebled heart failed also.

In some cases, when vomiting persisted and was tending to become overflow in character, I have left the stomach tube *in situ* during the operation, or if the stomach and upper intestine were found distended when the abdomen was opened, I have passed it again.

The next indication is to restore as far as possible the depleted body fluids which have been extracted from the tissues everywhere. The increasing diminution of the chlorides of the blood has apparently a great deal to do with the recuperative powers of the patient; the loss of these chlorides must be made up, but no excess be given. Therefore give, according to the size of the patient, the state of his heart, and the effect on his pulse and general condition, intravenous, subcutaneous, and rectal infusions of saline solution. His tissues will tend to take it up rapidly, so encourage absorption by making the solution isotonic. The saline may have to be given before or during the operation, as well as later on. In the most severe cases it may be necessary to give hypertonic saline, as Ross has recommended.

I think it is better not to give active aperients after operation until the bowel has had time to recover its tone. Such a stimulus may, I believe, have the opposite effect to what is desired and cause the debilitated bowel to cease to function. I prefer to give enemata, to empty the bowel from below so that less strain is required to push on what may come along from above, and at the same time I try to coax back vitality and vigour and co-ordinate movements in the injured part by such simple remedies as belladonna by the mouth, or, if sickness threatens, atropine or eserine hypodermically in small doses. The first enema is usually given on the day succeeding that of operation. When evidence of activity becomes manifest in spontaneous passage of flatus or faeces or even by desire to go to stool, then I give, for example, small repeated doses of cascara and belladonna, or even a dose of castor oil and laudanum. As soon as the patient feels desire for it, I give him ordinary food so as to stimulate normal peristalsis and prevent noxious adhesions.

The part of the bowel which has been strangled tends to form adhesions. On more than one occasion I have had to open the abdomen again on account of fresh obstruction from this cause. Sometimes, if the bowel has been severely congested and dilated, although it may recover its colour quickly at operation, it may require several weeks before it works properly; in these cases the pulse remains abnormally rapid. Both feeding and the administration of medicinal intestinal and cardiac stimulants may have to be carefully regulated.

In discussing actual operative measures I wish first to lay stress upon the situation and manner of the incision. I almost invariably make a long, at least six inches, paracentral incision on the right side, a good inch from the mid-line, and displace the rectus from the mid-line outwards. I like to infiltrate the area of incision with 1/2 per cent. novocain solution (*plus* adrenaline) so that I may, if necessary, carry the making of the incision under *local anaesthesia alone at least as far as the peritoneum* and at the end of the operation be able to close the abdomen without more general anaesthetic than may have been required for intra-abdominal manipulation. This reduces the length and strain of general anaesthesia very greatly, and it is a much more simple business than making, for example, paravertebral injections. A short gas and oxygen anaesthesia will not harm the patient unless his condition is very desperate. I think that the long incision, by permitting easier examination and handling, more than makes up for the extra time expended on it. When sutured in layers post-operative hernia is avoided more by this than by any other method of making a long incision.

Having opened the abdomen, the hand is inserted into the lowest part of the pelvis and pulls up any collapsed coils there. The collapsed bowel is then followed upwards *until the point of obstruction is reached.* If no collapsed bowel is found in the pelvis the caecum is examined. If the caecum is collapsed the obstruction must be above it; if distended, then the obstruction is below it, so the sigmoid is next inspected; if this is collapsed the obstruction lies between the caecum and sigmoid. When there is much difficulty in arriving at a diagnosis of the site of obstruction I allow the distended coils of bowel to come out of the abdomen, but I cover them carefully with warm dry towels and gauze strips to prevent undue cooling. There is really no necessity for more elaborate apparatus. I prefer dry material to moist material; the latter, by its evaporation, fosters cooling of the bowel. If warm lotion is continuously poured over it in order to obviate cooling there results a sloppy mess besides the introduction of extra risk. I do not think that evil results follow the use of dry material so much as when moistened packs are used.

After finding the obstruction further proceedings range from the mere snipping of a band to the difficult and tedious separation of adhesions, short-circuiting, or the actual excision of a gangrenous loop followed by entero-anastomosis. In the last case I prefer to make end-to-end anastomosis whenever possible. If the patient is very bad it may be compulsory, after dealing with the cause of obstruction, simply to bring the gangrenous loop well out of the abdomen, fix the viable proximal and distal parts of the bowel to the edges of the wound, and open the loop. One or more enterostomies should be made above the affected loop through separate small wounds. Enterostomies, reserved for the worst cases, procure the advantage of draining different parts of the bowel and at the same time permit the introduction of saline solution. Every surgeon of experience knows how inert the bowel may become, and though drainage effectively empties one loop, adjacent loops may remain distended. The bowel kinks very readily in such circumstances. The saline solution must be introduced at very low pressure—over-distension prevents recovery of tone, besides tending to cause kinking. I believe that the performance of enterostomy gives better results than emptying the proximal bowel during operation. The latter procedure demands too much handling of the bowel and tends to increase shock; the same remark applies, of course, to wide excision of the bowel. In the

most desperate cases it is permissible only to make enterostomy, under local anaesthesia. In such cases I think that one opening should be made in the bowel by incision above the umbilicus and another well below it. The upper opening will combat the proteose toxaemia, the lower will combat the septic toxaemia.

It is sometimes difficult to decide when to perform enterostomy. I believe that if strong colicky pains have persisted right up to the time of operation and if, at the actual operation, the bowel responds to local stimulation, such as pinching, it will likely recover without enterostomy. If, however, the colicky pains have become feebler, if general distension of the abdomen is present, and if, at operation, the coils are found to be in any degree flaccid and floppy and do not respond definitely to local stimulus, enterostomy is compulsory. In cases of doubt, rather make an enterostomy than not. Vomiting will not get rid of the toxin, nor will a paretic bowel pass it downwards. As Wilkie of Edinburgh pointed out, paresis of the bowel is an important contributory factor to toxic absorption. The bowel will not recover unless the toxic contents are removed. If the obstruction has been in the large intestine I like to make a caecostomy as well as an enterostomy. In cases of this degree of severity I should also administer 20 per cent. hypertonic saline intravenously.

Sir William Taylor of Dublin has given indications as to the likelihood of having to perform enterostomy in cases of obstruction. Roughly speaking, according to him, the necessity corresponds to the stage of the illness, and he defines three stages. In the early stage it is only necessary to treat the cause. In the second stage, when distension of the bowel has occurred, the obstruction should be relieved and jejunostomy performed. Drainage may be required for only twenty-four to forty-eight hours. In the third stage the condition of the patient is so bad that it will not permit exploration, therefore jejunostomy only should be done, and later on, if the patient recovers, the obstruction may be dealt with. In my opinion that "if" is a big one; I prefer to ascertain what the pathological condition inside is. There is practically no hope for a patient who has to deal with, for example, a gangrenous loop of bowel in his interior. Enterostomy alone will not save him. Before giving up all thought of exploration, I like to see the effect of stimulation by drugs, intravenous infusions of saline solution, and blood transfusion.

In making an enterostomy, I think a Pezzier's catheter is a suitable tube to use, and of a medium size, but an ordinary large catheter serves the purpose equally well and is easier to remove. The latter has to be fixed by suture. Only exceptionally are there solid particles in the small intestine, so that the contents drain through comparatively small tubes.

I prefer to make the enterostomy, when the condition of the patient permits, after drawing the selected loop of bowel through a hole made in the omentum. When practicable, the tube is inserted in the bowel in a manner similar to the Witzel method employed in gastro-enterostomy, but in many cases one has to dispense with this refinement and simply insert the tube through a straight puncture, surrounding it by a purse-string suture. One of the fine chromic catgut sutures is left long and is used to moor the bowel to the abdominal wall. The loop of bowel is pushed back through the hole in the omentum, which is then made to lie snugly around the tube. If the enterostomy has been made from the exploratory incision, I draw the tube, before inserting it into the bowel, through a new small incision in the abdominal wall; this is usually most suitably made somewhere to the left of and slightly above the umbilicus. By this precaution contamination of the main wound is avoided. For suturing such easily torn bowel as is met with in this condition the so-called "atraumatic needle" advertised by the London Hospital appeals to me. The traumatizing "catch" of the thread at the eye of the needle experienced when ordinary needles are used may tear and cause a leak.

After multiple enterostomy I like to remove one tube at a time, the upper before the lower. The upper part of the small intestine seems to recover tone more quickly than the lower; the character of the toxin producing the paresis of the bowel may account for this as well as the fact that the paresis has usually been present in the lower bowel for a longer time. I have an impression that the higher the enterostomy the longer it takes to heal. The tubes may be removed and the stomata allowed to close as soon as the patient is established in convalescence—that is, really, when vomiting has stopped and the bowels have "moved" satisfactorily. Evacuation of toxic contents is one important factor, but restoration of peristalsis is also essential to recovery.

A simple application for preventing excoriation of the skin round an enterostomy is ethereal rubber cement solution (1 in 4) applied several times a day. The ether evaporates and leaves a thin film of rubber over the skin.

It is sometimes almost impossible to tell, from the appearance of the bowel, whether the colour and the swelling are due to intense congestion and subperitoneal or interstitial haemorrhage alone or whether gangrene has actually occurred. The presence of the haemorrhagic effusion constitutes the difficulty. The purple colour of mere congestion soon gives way to a more normal appearance when strangulation is relieved, but effused dark blood does not dissipate and there may be no change of colour or only in patches. Of course, the discoloured, flaccid, inert, and often brittle state of the really gangrenous bowel is easy to distinguish—but there are all gradations. It must be remembered also that interstitial extravasation of blood has probably taken place before gangrene has occurred. I have never found the following test to fail, though I have used it for many years. I incise, with a sharp knife, the peritoneum and very superficial fibres of the muscular coat of the suspected part of the intestine. If the circulation is intact, definite bleeding, although possibly in small amount, will occur. It is found, then, that each time a clean piece of gauze is pressed lightly on the incised part it will be stained with fresh blood. Viability of the bowel is still more certain if the blood can be seen oozing steadily from the cut. If gangrene has occurred, the first or second piece of gauze may be definitely stained, but not more. There is practically never any doubt in actual experience. If the gut is viable the small incision is closed by a mattress suture of fine linen or catgut.

PYELITIS FROM INFECTION WITH MORGAN'S NO. I BACILLUS.

BY

D. RIDING, M.D., M.R.C.S., L.R.C.P.,

ASSISTANT GOVERNMENT BACTERIOLOGIST, WELLCOME TROPICAL RESEARCH LABORATORIES, KHARTOUM.

As I have been unable to find any reference to urinary infection with Morgan's No. I bacillus, I think that the following two cases are worth recording. The association of this bacillus with infantile diarrhoea, and as a concomitant organism in bacillary dysentery due to the bacillus of Shiga and Flexner, is generally recognized. Recently I have found this organism in the faeces of many patients suffering with symptoms of bacillary dysentery, when repeated attempts have failed to isolate any other dysenteric organism. While believing it be pathogenic, I had no positive proof of this until I isolated it from two cases of very definite pyelitis.

CASE I.

Private L., aged 24, a British soldier at Khartoum, stated that while in India (Agra) he had the first symptoms of his present condition. In February, 1923, he had a sudden sharp pain in the left side, which remained localized, was worse when he was in bed, was not propagated, and had no relation to micturition. For several days he had frequency of micturition and noticed that his urine was thick. The acute symptoms passed off in a fortnight on the exhibition of urotropine. Two months later (in April, 1923) he had a similar attack; pus was found in the urine, but no blood or casts were seen.

No further symptoms occurred until November, 1925, when he had to be relieved on guard duty because of a sudden onset of acute pain in the left lumbar region. The symptoms again passed off in ten days, but a further attack occurred only one month after. A radiogram then taken showed no detectable pathological condition.

The present attack, when the patient first came under my notice, was on March 15th, 1926. While on police duty he was

seized with pain in the left lumbar region; it was unaccompanied by any nausea, or alimentary or urinary disorder, although he admitted having a slight headache. There was some tenderness over the left kidney, but none over the left ureter or bladder.

While in hospital the patient had slight pyrexia in the evenings of the first three days—98.8°, 99°, and 99.2°—and again on the seventh, eighth, and ninth days of 100.8°, 99.2°, and 98.8°; the rise in temperature was associated each time with an exacerbation of pain. The urine was alkaline and contained a trace of albumin and a heavy deposit of pus cells, with a few red blood corpuscles and epithelial cells; but no casts or crystals or other abnormal constituents, nor tubercle bacilli were found.

An organism giving the bacteriological characters of Morgan's No. I bacillus was grown in pure culture. This organism was again isolated on March 25th, April 15th, and April 18th, each time in pure culture. A blood culture made on April 8th remained sterile. The results of agglutination tests of the patient's serum against the bacillus isolated proved interesting. Using Professor Dreyer's macroscopic technique, the following results were obtained: On April 2nd, agglutination in a dilution of 1 in 125 in an hour; on April 20th, agglutination in a dilution of 1 in 500 in an hour. In each case a normal human serum was put up as a control. The patient had the first three doses of an autogenous vaccine in the interval between the two agglutination tests.

CASE II.

The second case occurred in a British subject who was in the Khartoum Civil Hospital in February, 1926. He had a typical attack of pyelitis with pyrexia which lasted about three weeks. The urine was alkaline and contained a heavy deposit of pus cells and many coliform bacilli. I isolated Morgan's No. I bacillus from the urine, but in this case there were a few *B. coli* colonies present also.

The organism in each case gave the following cultural characteristics, etc.: On agar slopes a thin yellowish-white film was formed, having a sticky feel when touched with the platinum wire, while small colonies closely resembling *B. dysenteriae* were grown on MacConkey's medium. In broth a diffuse turbidity was produced. The bacillus was motile and Gram-negative.

The usual sugar reactions were tested. The result was alkaline with litmus milk; acid and gas with glucose and with galactose; acid on the fourth day with glycerol, and slight with indol. In tests with all the other substances there was no reaction.

Conclusions.

While the findings are very definite in Case I, they are more doubtful in Case II.

Both patients are receiving vaccine treatment, an autogenous vaccine having been prepared in each case.

EXTENSIVE DIVERTICULOSIS WITHOUT SYMPTOMS.

BY

NORMAN L. CORKILL, M.B., CH.B.,

HOUSE-SURGEON, DAVID LEWIS NORTHERN HOSPITAL, LIVERPOOL.

THE following case is notable as indicating the existence of extensive diverticulosis for at least fourteen years without giving rise to symptoms. Other pathological conditions were also present within the abdomen, including congenital abnormality of the small intestine.

A married woman, aged 51, who had borne six children and had a tendency to obesity, was admitted to the David Lewis Northern Hospital, Liverpool, on May 3rd, 1926, under Mr. G. C. E. Simpson. She complained of "wind" since an operation in 1912, and stated that for the last year she had suffered from occasional attacks of pain in the epigastrium, occasionally going through to the right shoulder-blade; they had no relation to food, and occurred irregularly either by night or by day, were sometimes accompanied by jaundice, and invariably by vomiting. The vomit was frothy, yellowish, and tasted sour. She said she had had typhoid fever when 6 years of age. On February 21st, 1912, she was operated on for gall stones, and five months later a hydatid cyst of the left hepatic lobe was removed. Both operations were performed by Mr. Murray at this institution. She brought to hospital with her a copy, which she herself had made at the time, of her old case-sheets, and also the two summary sheets dealing with the operations. On the back of the first summary sheet was found a pencil drawing of a portion of large intestine showing diverticulosis of the mesenteric attachment. This, she said, was drawn by Mr. Murray in the out-patient department to illustrate her condition. Mr. Simpson, who was then assistant honorary surgeon, remembers the occasion well.

Condition on Admission.—She was slightly jaundiced, the tongue was coated, and the breath foul. She was not constipated. Nothing abnormal could be discovered in the abdomen, and Murphy's sign was not elicited. Faeces and urine contained no abnormal constituents. A fractional test meal showed the presence of blood and bile in the stomach, with 0.03 free hydrochloric acid and 0.07 active.

Operation.

Mr. G. C. E. Simpson opened the abdomen on May 10th, when slight hepatoptosis became evident. The gall bladder, which was adherent to omentum, was full of small faceted stones. The pancreas and the appendix were in a state of marked chronic inflammation. From the caecum to the beginning of the rectum were hundreds of diverticula containing beads of faeces, and varying in size from that of a pea to that of a cherry. They were of the acquired type[1]—that is to say, they were hernial protrusions of mucosa. The vast majority were in the concavity of the mesenteric attachment and the appendices, but there were also numerous small protrusions through the taeniae and peritoneum-covered muscular wall. The contents of all those in which it was attempted could be emptied easily into the bowel. There was no evidence of inflammatory reaction round these diverticula, and Mr. Simpson was able to say, having seen the case in 1912, that the only notable progress was an increase in size.

Another interesting condition present was an arrested rotation of the small intestine. The duodenum, with the superior mesenteric artery on its inner side, turned back on the head of the pancreas in the shape of a double S. The duodeno-jejunal flexure was at McBurney's point, the mesentery running thence upwards to the left. The mesenteried caecum, which was entered by the ileum from the right, was slightly left of the mid-line in the upper umbilical region. This arrest had apparently occurred at the eleventh week after the caecum had entered the abdomen through the narrowing umbilical orifice.[2] The gall bladder and the appendix were removed; the colon, with its diverticula, being symptomless, were left.

The patient made an uneventful recovery, leaving hospital in very satisfactory health.

I am indebted to Mr. G. C. E. Simpson for permission to publish this case.

ULTRA-VIOLET LIGHT FROM OPEN ARC WITH TITANIUM ELECTRODES.

BY

ARTHUR ROBERTS, T.D., F.R.C.S.,

MAJOR R.A.M.C.(RET.),

CONSULTING AURAL SURGEON, ROYAL BERKS HOSPITAL, READING.

IT is now established that ultra-violet light has important biological effects. Many diseased conditions have been treated with it and much enthusiasm has been evoked over its possible therapeutic value. It has been pointed out that if a list of the diseases said to have been benefited was made it would probably begin with acne and go through the whole official nomenclature to zona, including housemaid's knee and the minor psychoses. But the fact that its value is in many cases overstated and its mode of action is at present rather mysterious is no reason why its effects should not be thoroughly explored.

GENERAL.

The rather widespread impression that these rays are dangerous is illusory. They cause nothing comparable to the injuries that may follow the imprudent use of *x* rays. Their penetration is very slight and confined at the most to the lower layers of the epidermis. Even at this slight depth we begin to recognize two kinds of action, depending upon the degree of exposure and the precise wave-length of the light employed. It is at present difficult in medical practice to restrict the wave-length to any narrow degree of the ultra-violet spectrum. Where this has been done experimentally we have evidence that rays beyond the visible spectrum down to 290 $\mu\mu$, which have been spoken of as "biologic," are of such a nature as to stimulate biological processes, particularly as the lower limit is approached, whilst beyond this the still shorter rays, called "abiotic," exhibit a lethal action, though on account of their restricted penetration this is of little importance unless the exposure is prolonged. Even these shorter rays, if used with brief exposures, may perhaps act biologically. Taking the germicidal effect as a test, Browning and Russ got a maximum effect between 280 and

255 $\mu\mu$. Hausser and Vahle obtained the maximal erythema effect on the human skin between 300 and 290 $\mu\mu$. Leonard Hill found that rays at 275 $\mu\mu$ killed infusoria in twenty minutes, that rays at 275 and 257 $\mu\mu$ produced erythema, whilst rays at 232 $\mu\mu$ were ineffective (using the lines in the cadmium arc). As regards penetration, he found that under certain conditions rays shorter than 330 $\mu\mu$ did not penetrate what he describes as a thin layer of the horny epidermis, which resembles in this a 3 per cent. solution of quinine. It might here be pointed out that the solar radiation available at the earth's surface does not include rays shorter than 300 $\mu\mu$. The eye is more transparent to ultra-violet radiation than the external skin. The cornea is transparent to rays longer than 295 $\mu\mu$, and the lens is the chief barrier to ultra-violet rays reaching the retina. Probably no rays shorter than 380 $\mu\mu$ can reach the retina. Conjunctival inflammation from exposure to ultra-violet radiation generally subsides rapidly and is strictly comparable to the inflammatory effect which such radiation has on the skin.

The effect on the blood of exposure to ultra-violet rays has been studied by Koopman amongst others. He found the concentration of erythrocytes to be unchanged; the leucocyte count at first increased, then fell; the lymphocyte count became more permanently increased. Clark points out that this depends upon the wave-length. Rays of 400 to 300 $\mu\mu$ cause leucopenia, rays of 300 to 200 $\mu\mu$ produce lymphocytosis. Balderry and Barkus found that exposure to ultra-violet rays increases the alkalinity of the blood, and thus runs parallel to the degree of pigmentation. Pech has recently pointed out that there seems to be an antagonism between the red end and the violet end of the spectrum so far as the characteristic effects of ultra-violet radiation are concerned. If this is correct it tends to indicate that the source of the radiation should possess as little as possible of the red end, and suggests that the carbon lamp falls short of an ideal source. Evidence also has been advanced that exposure to ultra-violet rays increases the metabolic rate, but the proof at present is incomplete.

The most impressive and important observations are, however, in relation to the effects in such deficiency diseases as rickets, and it seems legitimate to assert definitely that such diseases may practically be cured thereby. And here we may also refer to the exalted resistance to disease which exposure to ultra-violet rays brings about, and which accounts for the beneficial effect of sun-ray treatment in such diseases as tuberculosis.

Mode of Action of Ultra-violet Rays.

At present we can do little more than speculate on the mode of action of ultra-violet radiation. It appears necessary to revise our views somewhat as to the functions of the skin, or at any rate its deeper layers (Malpighian layer). It has long been recognized to be a protective covering and a mechanism for the regulation of the temperature of the body. But in recent years evidence has been accumulating that it may possess other functions—notably that of acting as a regulator of internal functions by means, perhaps, of secretions formed in its deeper layers. It may, indeed, play a direct part in the general metabolism of the animal body.

In order to influence this possible cutaneous metabolism it is, of course, essential that any environmental stimulus should penetrate the external protective and indifferent layers of the epidermis. It is conceivable that part of the advantage accruing from the old practice of blistering, or the application of mustard poultices, lay in the indirect stimulation of the deeper layers to appropriate secretory activity rather than in the excitation of superficial nerves which seems to be involved in the older explanations of the efficacy of "counter-irritation." The undeniable advantages of the effect of sunlight and the different forms of light-ray treatment seem most probably to depend upon certain radiations of sufficient penetrating power stirring up the activity of the Malpighian layer of the skin, and thus leading to an augmentation or modification of their processes. But evidence has lately been adduced that some of the longer rays may actually penetrate into the dermis.[1]

The Source of Ultra-violet Radiation.

I have been engaged now for some twelve years in studying the effects of radiations from different sources upon the body, particularly in different diseased conditions. In my experience the most potent rays are from metallic arcs in which titanium is the prevailing element. Titanium rays are rich in lines in the extreme ultra-violet, and are of great potency when applied to bacteria. There is a rich line spectrum also in the region of 300 $\mu\mu$. The richness of the bright lines in the ultra-violet region in the case of titanium radiation means considerable effect with short exposures. Three minutes' exposure of the naked body may bring a tingle to the spine, and with repetition produces pigmentation. In the majority of cases two or more baths produce marked results. Patients who are mentally disturbed are benefited, and many forms of anaemia react to this ray treatment. Examination of the blood before, during, and after treatment has demonstrated in some cases a rapid return to a normal condition and to a permanent improvement.

For the purpose of treatment a suitable apparatus has been designed to operate from one to twelve arcs, and applicable in either the standing or recumbent position.

A comparison of the spectra from the titanium arc with those from iron and carbon arcs makes it clear that the radiations from the titanium arc are very rich in rays of shorter wave-length.

I have been greatly assisted by my technical colleague Mr. W. G. Moore, who has designed special apparatus and electrodes for the different forms of treatment.

Cases.

Of the many different kinds of cases I have had under treatment during recent years I will report some in which a diseased state left what is presumably chronic fibrosis.

Case A.—A woman, aged 28, with chronic arthritis. At the age of 18, during a course of nursing, she developed rheumatic fever. She recovered and resumed duty, but would constantly have to go off duty on account of pains in the wrists and ankles. Eventually she had to give up work in April, 1918. In September, 1918, many joints became affected and gradually got worse until November, 1920, when she went into Bath Hospital, remaining until February, 1921. In March, 1921, she had her tonsils removed. In April, 1921, she went into another hospital and had the legs, which were drawn up, put into plaster and straightened under an anaesthetic. No improvement followed. When this patient came to me she could only walk feebly with assistance, and suffered much pain. All her joints were swollen; there was complete fixation of knees, hips, and elbows; the ankles and wrists were also affected. It was decided at first to try and improve the knees, ankles, and wrists. For this the rays were applied daily focally for three minutes. After four days the rays were applied to the whole body and light massage given to the joints. At the end of a month the patient could walk and flex the knees. At the end of nine weeks she was able to walk well, going up and downstairs, getting in and out of buses, etc. She is now at her home in the country doing household duties, and taking good walks.

Case B.—A man, aged 75, was received as a case of "arthritis" dating from 1915; he had been confined to bed for eighteen months. On examination there was almost complete fixation of the knees and hips, and the tissues around felt hard. He suffered almost continuous pain, could only stand for a few minutes and walk but a short distance. He had tried many kinds of electrical treatment without deriving benefit. The rays were applied focally to the base of the spine, hips, and knees every other day for two weeks, followed by light massage. They were then applied to the whole body in the hope of improving the general health. After two months there was a marked improvement, and at the present time the patient is free from pain and can walk a considerable distance. He expresses himself as feeling a different man.

Case C.—A doctor, aged 50, had suffered for years from Dupuytren's contraction of the right forefinger, and had been advised that surgical intervention was the only remedy. The hand was exposed to intensive rays for periods of from four to five minutes. After ten treatments the tissues became softened and the finger could be straightened. The improvement is maintained.

Case D.—A woman, aged 30, had suffered with severe varicose veins of the legs, which had both been operated on. She was sent to me complaining of pain in the ankles which prevented walking, and also kept her awake at night. On examination both external ankles were found to be swollen and varicosed. Intensive rays were applied every other day for two weeks, after which the pain disappeared. The rays were then applied twice a week for a fortnight, and the condition further improved. The patient can now walk long distances, play golf, etc., without any discomfort.

Case E.—A woman doctor, who had suffered for years with chilblains on both feet, had endured much pain and could get no relief. Focal radiation was applied to the feet for periods of three to five minutes twice a week. After ten treatments the chilblains disappeared, and although cold and wet weather prevailed she had no recurrence.

Case F.—A man, aged 57, with severe anaemia, diagnosed as probably pernicious. The blood count at the commencement of treatment (September 23rd, 1924) was as follows: Red blood corpuscles 2,600,000, white corpuscles 23,000, haemoglobin 46 per cent. Counts taken at monthly intervals showed a gradual improvement, and the last count, taken in April, 1925, showed a decrease of white blood corpuscles to 9,000 per cubic millimetre. The patient when last seen seemed practically normal.

Another type is seen in the following case.

Case G.—A man, aged 35, with neurasthenia of some years' standing. He was melancholic, had lost his grip on life, and had to give up his work. He suffered from insomnia and loss of memory. In this case the whole body was treated for three minutes every other day, gradually increased to four and a half minutes. There was marked improvement at the end of two weeks. At the end of a month he was able to take a fresh post, and I understand that he has not suffered since.

These cases are only samples, and I feel convinced that titanium rays, used with discretion, are frequently of extraordinary value. When there is an obvious psychological element in the diseased condition titanium rays are often of extreme value, but I believe that the improvement is out of all proportion to the mere "psychical appeal" a course of treatment involves.

At the present stage it has been deemed advisable to withhold treatment in certain cases, but the success attending such a large percentage of those who do come under treatment seems to justify further strenuous investigation. It may be pointed out that three to four minutes' exposure to the titanium rays is equal to many hours of the sun's rays. Considerable caution is required in the selection of cases. At present phthisis in an advanced stage is one disease for which these rays should never be used.

Among other forms of disease in which the results of this treatment are highly encouraging are tuberculous wounds, septic and irritant conditions of the skin, sciatica and lumbago, etc., but space will not allow me to deal with these in detail at the present time.

I append some controlled laboratory observations on the bactericidal effects of titanium rays. I quote these as indicating the richness of the radiations in the extreme ultra-violet.

"Experiments were carried out with the titanium rays as evolved in the apparatus used in the treatment of patients. Petri plate cultures were used, one series containing twenty-four-hours' cultures of the test organism, and the other thickly sown with the respective test organisms an hour before the exposure. To avoid the temperature factor the rays were used openly, and not focused on the plates. The results were as follows:

"A. *Pneumococci.*—A twenty-four-hours' culture on blood agar was exposed for five minutes to the rays. Some of the growth was then removed and inoculated into blood agar tubes. No growth of the organism was obtained after forty-eight hours' incubation at 37° C. A similar plate not exposed, and kept as a control, gave rich subcultures under the same conditions of incubating. A blood agar plate thickly spread with a young culture of the pneumococcus was exposed to the rays for five minutes and then incubated for forty-eight hours. No growth of organisms took place except at one margin where there was a fringe of colonies at the outer circumference of the medium. This was found to be due to the holder casting a shadow at the lower extreme edge of the plate, and so this area unavoidably escaped subjection to the rays. A control plate of pneumococci similarly spread and incubated yielded a rich growth of the organism.

"B. *Streptococci.*—A *Streptococcus pyogenes* plate showing twenty-four-hours' growth of the organism and exposed to the rays for five minutes was sterilized, no growth of the organism being obtained. The control plates gave rich growths. The newly spread plate of the streptococcus submitted to the rays showed no growth except at the extreme margin where shadow was unavoidable. The control plate showed a rich growth under similar conditions of incubation.

"C. *Typhoid.*—A *B. typhosus* plate culture containing a confluent growth of twenty-four hours was sterilized by five minutes' exposure. Subcultures could not be obtained. The newly spread plate of *B. typhosus* exposed for five minutes gave no growth of the bacilli except at the extreme margin where the shadow prevented exposure. The control plate showed a rich growth of *B. typhosus.*

"D. *Anthrax.*—A forty-eight-hours' culture of *B. anthracis* showing spores was spread on agar plates and one of them given ten minutes' exposure, the extra time being allowed to compensate for the very resistant character of the spores of this organism. After forty-eight hours' incubation the exposed plates showed growth of the bacillus at the shadow margin and a very occasional colony towards mid-centre of the plate. The control plate showed rich confluent growth, and on comparison it was seen that the control plate contained at least 90 per cent. more growth than the exposed plate, not counting the colonies at the shadow margin, which it is fair to regard as an unexposed portion."

ADVANCED TETANUS CURED BY INTRATHECAL INJECTION OF ANTITOXIN.

BY

BERTRAM MUIR, M.B., B.S., F.R.C.S.,

SURGICAL OFFICER TO K.M.A. MINES AND CHINESE GOVERNMENT RAILWAYS, *TONGSHAN, NORTH CHINA.*

THE *prophylactic value of antitoxin* was fully established during the war, but even at the end of it doubt was expressed as to its value in the treatment of the clinically declared disease. Permin and Faber,[1] quoting Danish statistics, give a mortality of 79 per cent., the prognosis varying directly with the incubation period prior to development of the primary symptoms. Cases developing symptoms in ten days or under from the primary trauma show a mortality of over 90 per cent. British cases in the war showed a mortality of 50 per cent., the common causes of death being cardiac failure and exhaustion.

In considering the treatment of declared tetanus the pathology has to be taken into account. A combination has formed between the toxin and the motor nerve cells of the central nervous system, toxin is circulating in the blood, and is still being manufactured in the wound.

Sherrington's experiments on monkeys showed a 56 per cent. cure of experimentally established tetanus by intrathecal injection of antitoxin. The early researches of Sicard[2] showed much quicker results in the time of onset of spasms by injecting tetanus toxins into the subarachnoid space than by the intravenous or subcutaneous routes. Hence, *per contra*, antitoxin administered intrathecally should act more powerfully and quickly than by the other routes.

The case about to be described illustrates the value of treating the various pathological phenomena of established tetanus by the intrathecal administration of powerful doses of antitoxin, by supporting the patient's heart and general system during the muscular spasms, and by removing promptly the site of infection.

A Chinese boy, aged 12½, had his left leg crushed in its middle third by the wheel of a Chinese cart. A bad compound comminuted fracture of both tibia and fibula was the result, and the native doctor was immediately called to attend.

The child's condition became progressively worse, and on the ninth day following the accident he was brought to hospital. Below the seat of injury absolute dry gangrene had been established, and when the patient was lifted off the stretcher the lower part of the leg fell off. There was no haemorrhage. The child had fever (102° F.) and a rapid pulse (120), and definite head retraction was present, with masseteric spasm and the typical "risus sardonicus" of declared tetanus.

In view of these facts I at first refused to operate, but, on the pleading of the parents, attempted what I regarded as a forlorn hope.

The child was given morphine 1/6 grain, and put under ether anaesthesia. A pint of intravenous saline was administered and a rapid circular amputation performed at the seat of election, no attempt being made to suture flaps. Two premolar teeth were extracted with difficulty to permit easy feeding, and then a large intrathecal injection of antitoxin was administered.

Arguing on the principle that the lumbar enlargement of the cord was the site of attack, the lumbar puncture needle was introduced through the eleventh dorsal intervertebral space, and about 15 c.cm. of cerebro-spinal fluid drained off; 20 c.cm. of standard antitoxin, representing 20,000 units, were then injected. The shoulders and pelvis of the patient were raised, in order to make the site of injection the most dependent part, for four minutes, and 4,000 antitoxin units were then administered subcutaneously.

On the next day typical opisthotonic and pleurothotonic spasms were present; the trismus was much worse, and there was considerable rigidity of the rectus abdominis muscles. The temperature was 101°, and the pulse 134. The wound was slightly septic. A further intrathecal injection at the same site, of 20,000 antitoxin units, was administered, and followed by 10,000 units subcutaneously. Mouth-feeding with a tube and funnel was established through the dental space previously prepared, and rectal saline (10 ounces, with 5 per cent. glucose and 30 grains of potassium bromide) were administered every four hours.

On the third day the temperature was 100°, and the pulse 126; opisthotonos and trismus were present; 4,000 units were administered subcutaneously, and salines and tube feeding were continued.

On the fourth day the opisthotonos was very slight, but trismus persisted. The temperature was 99°, and the pulse 118; 4,000 units were again administered subcutaneously, and rectal and tube feeding continued.

On the fifth day opisthotonos had practically disappeared, and there was a slight relaxation of the masseteric spasm. The child's general condition was much better.

On the sixth day all spasm had practically disappeared, although there was some difficulty in swallowing, and tube feeding had to be continued. The masseteric spasm completely disappeared with the dysphagia; the child made an uneventful convalescence, the stump healing by granulation; he left hospital on the twenty-eighth day.

This case illustrates how the energetic and persistent symptomatic treatment of an apparently hopeless case of tetanus was rewarded. It appears to justify the claims made for the value of the intrathecal injection of antitoxin, and I consider that intrathecal injection at the anatomical site of the anterior horn cells of the spinal cord, supplying the injured muscles which are the actual seat of toxin manufacture in the wound, is all-important for its success. In this case the lumbar enlargement of the cord was fully impregnated with the antitoxin, and this appeared to be the successful factor in the case.

Memoranda:
MEDICAL, SURGICAL, OBSTETRICAL.

CARCINOMA OF THE THYMUS GLAND.

A SHORT time ago I examined a man who complained of gnawing, but not severe, pain in the region of the junction of the cartilages of the eighth and ninth ribs on the right side. It appeared to be a case of intercostal neuralgia. There were no other symptoms so far as I could discover.

Treatment was continued for six weeks, but did not relieve the pain, and there was increasing anaemia and some wasting. Later a small triangular area of dullness with tubular breathing was detected behind, close to the spine, and I informed the relations that probably cancer of the lung was developing, and was the cause of the symptom of severe pain in the region mentioned from pressure on the intercostal nerves. No expectoration.

X-ray examination showed cloudiness and small dark areas over the lungs. The radiologist suspected tuberculosis, but it was obvious that the dark areas were due either to byssinosis—the patient was a collar cutter by profession and ran a small private factory of his own—or else that the areas were secondary deposits over the lungs. Irregular temperature, but not a daily one, developed, and, as was to be expected, pleural exudation took place. On several occasions large quantities of fluid were removed; microscopical examination of this gave negative results.

As the relatives were always in doubt as to the cause of the illness, a *post-mortem* examination was allowed; this showed well marked massive cancer near the root of the right lung with secondary nodules in both lungs. On the right the growth was adherent to the dome of the diaphragm, which was perforated, and there was a fan-shaped involvement of the liver. One possibility was that the carcinoma started from the mucous glands of the larger bronchi at the root of the lung, and that the secondary nodules arose along the lymphatic vessels surrounding the bronchi. The second and most likely supposition is that the cancer started in Hassall's corpuscles in the only partly atrophied thymus gland.

The microscopical report is as follows: "The section shows a malignant new growth composed of irregular angular cells. It may be derived from a growth originating in Hassall's corpuscles of the thymus, but further information about the history is desirable."

May I offer the suggestion to those who so ably work on the cancer problem that humanity may become susceptible to cancer when the thymus gland does not completely atrophy, but takes on an altered function, producing a blood plasma saturated with thymic juice, rendering the body thus susceptible to cancer organisms (?), and that any local source of irritation which lowers the organ's resistance allows cancer to originate and settle in that locality?

Ashford Middlesex. JOHN REID, M.D., D.P.H.

A LARGE VESICO-URETHRO-VAGINAL CALCULUS.

THE two reports on vaginal calculi published in the JOURNAL by Lieut.-Colonel W. F. Brayne (January 2nd, 1926, p. 17) and by Mr. E. Farquhar Murray (February 6th, 1926, p. 238) prompt me to record the following case:

A married woman, aged 52, was admitted to the Mansfield and District Hospital under the care of Dr. Hunnard for incontinence of urine.

She stated that a year earlier she began to suffer from frequency and pain at the end of the act of micturition, but fearing that it might be a cancer she did not consult a doctor. The intermittent attacks of pain subsided to give place to a persistent aching. At first she had some control over micturition, but none for six months. The urine was thick and foul-smelling, and she was very distressed on account of the bad smell emanating from her, and by fear of cancer.

On vaginal examination a stone was seen projecting from the anterior wall of the vagina, wedged in a large gap about two inches long and one inch wide. The gap stopped short of the external meatus of the urethra. Urine was continually dribbling away from the upper part of the fistula. The stone was removed, and she had very severe cystitis; repair of the fistula was not attempted. The stone was white, smooth except at the top end, and more or less rounded. It weighed 4¼ ounces, and measured 4½ by 4 inches; its nucleus, according to *x*-ray appearances, consisted of oxalate.

Mr. D. Greig, the curator of the Museum of the Royal College of Surgeons, Edinburgh, to whom I sent the stone, considered it a rarity. At Dr. Hunnard's request I performed a plastic operation under spinal anaesthesia, six weeks after the first. The patient made an uneventful recovery.

I am informed now, after a year and a half, that she is in excellent health, and has full control over micturition, though she has slight frequency, having to empty the bladder every four hours, no doubt due to the fact that the bladder contracted during the time she had incontinence, and its capacity for holding the normal quantity of urine diminished.

I am much indebted to Dr. Hunnard for permission to publish this case.

M. SOURASKY, M.D.Leeds, F.R.C.S.Ed.,
London, W.1. Surgical Registrar, London Jewish Hospital.

AN ALTERNATIVE TO CIRCUMCISION IN PHIMOSIS.

AFTER many years in general practice, during the greater number of which I had a partner or employed an assistant, I was struck with the fact that not one of them knew that there was an alternative to circumcision in the treatment of phimosis. Therefore I infer that a good many others do not know it. It was taught me by my principal when I was an assistant in 1883. It is as follows.

With strict antiseptic precautions, an ordinary silver probe is taken in the right hand and with the left hand the foreskin is drawn back as far as possible, the orifice being slightly stretched. The probe is then insinuated between the glans and the foreskin, about the centre, and is coaxed back until the blunt point is seen or felt to have gone as far as the base of the glans. The probe is then gently worked laterally, first to one side and then to the other, so as to break down the adhesions between the mucous membrane of the glans and the prepuce. In doing this the point of the probe should be worked round as far as the fraenum on either side, and in bringing it out care should be taken to break down the adhesions which surround the orifice of the prepuce. Some cases have very few adhesions, and the little operation is quite easy. When the adhesions are more extensive, it can always be managed with a little patience. When done successfully it should be possible for the foreskin to be drawn back to the base of the glans quite easily. The surfaces should then be cleansed with boric lotion and smeared with carbolized oil, and the foreskin drawn forward again. The nurse should be instructed to draw back the foreskin once or twice a day, to prevent it adhering again. On several occasions, owing to not having a good nurse to hold the baby, I have had to complete the operation at a second sitting, but have nearly always managed it at one. On one occasion I damaged the fraenum in bringing the probe round. There never appeared to be any redundancy of skin afterwards, at all events none to cause inconvenience.

I have never come across a case in an infant which I could not manage easily. With one case in an older patient I failed.

ABORTION: MEDICO-LEGAL AND ETHICAL ASPECTS.

A JOINT meeting of the Medico-Legal Society and the Section of Obstetrics and Gynaecology of the Royal Society of Medicine was held on January 21st to consider the medico-legal and ethical aspects of abortion. Sir ARTHUR CLAVELL SALTER (Mr. Justice Salter) presided over a very large attendance.

The Medical View.

Dr. J. S. FAIRBAIRN began by outlining, for the benefit of non-medical members of the audience, the medical causes for which abortion might be induced, including diseases peculiar to pregnancy on the one hand, and on the other diseases which pregnancy aggravated or which made it particularly dangerous. In diabetes or kidney or heart disease there was general agreement that if the condition was serious and did not improve in spite of medical treatment, abortion might be induced. With regard to tuberculosis, certain forms of malnutrition, and certain nervous and mental states, there was divergence of opinion as to the advantages of terminating the pregnancy. In the case of women who had been insane in a previous pregnancy, the usual rule was that, if a second pregnancy followed soon, it should be terminated. On the other hand, if there had been some complication not likely to recur, such as excessive bleeding or septic infection, which was clearly the provoking cause of the mental disorder, it was usual to allow the pregnancy to continue. The commonest reason, especially in hospital, for interfering with pregnancy was that some damage had already occurred; in that case the treatment was not the induction of abortion, but the completion of an abortion already started. The original principle that guided the profession was that induction was lawful only if the woman's life was endangered by the pregnancy, but this had been rightly extended to include cases in which serious or permanent damage to health might result. During the last twenty-five years there had been an increasing extension of the practice, and many in the profession acted on the supposition that it was not unlawful to take into consideration other than purely medical factors, including social, economic, and eugenic reasons. The present meeting arose out of a discussion at the British Medical Association Annual Meeting in Nottingham (BRITISH MEDICAL JOURNAL, August 7th, 1926, p. 237), and Dr. Fairbairn drew attention to a case cited by the opener of that discussion—the case of a barrister and his wife who took the view that, "the prospective baby being theirs, it was their own affair whether they allowed their work to be completed or not"—as an instance of the casuistical arguments sometimes employed. The pregnancy was terminated in that case, on the ground that rapidly recurring pregnancies affected the mother's health, but within six months pregnancy happened again, and this time interference was refused, but the couple went to another doctor who was more pliable. The rule might be inferred "one abortion per patient," but it did not work, for what happened was "one abortion per patient per doctor"! The effect of the spread of loose views was to produce a vicious circle, for as the public learned that abortion could be easily procured under the guise of medical indications, each individual failed to see why her medical attendant should hesitate in her case, and thus pressure was put upon doctors. The causes of a lowered professional standard were the greater safety and more frequent resort to operative procedure through medicine, the effect of the attitude of the general public on the profession (the ethical standard had been greatly lowered from the same causes which had given an impetus to the conception-control movement), and the changed social conditions which made women more liable to depression and nervous exhaustion under the strain of child-bearing. He advocated that none other than purely medical considerations should be allowed to weigh, and dissented from the "hopelessly inverted" statement of the position by the opener of the discussion at Nottingham that "It is an ethical question of great interest to what extent we as doctors have the right to insist that a woman shall pass through an ordeal which she is unwilling to face, even if we do not think that she will sustain any permanent injury from so doing." It was not a question of "the right to insist," it was a question whether there was any right to interfere with normal pregnancy. This matter should be thought out in terms of hospital rather than of private practice. The private practitioner was more directly under the influence of his patients and their relatives; in hospital factors other than medical did not weigh, and unless her condition was very urgent the patient was kept under observation and treatment until it was seen that all other measures of relief had failed before abortion was induced. Abortion-mongering was but infanticide anticipated by a few months. Perhaps it was too much to expect the populace to think the non-sentient embryo of much account, but medical men knew that the little heart was beating very soon after the patient was aware that she was pregnant. The Soviet Republic of Russia had legalized abortion (BRITISH MEDICAL JOURNAL, October 30th, 1926, p. 802), and the spread of loose views in the profession regarding its responsibility must tend towards a similar state of affairs in this country. Medical indications alone should be considered in deciding on the induction of abortion; such indications should be defined as those clearly involving danger to life or health of mother, or damage to the pregnancy sufficient to interfere with its future development, and the onus of proof should rest on the practitioners concerned. In border-line cases observation of the patient away from home and failure of other methods of treatment should have proved abortion to be the only recourse.

Legal and Ethical Aspects.

Lord RIDDELL summarized the law relating to abortion. The legal position might be stated as follows: if the mother died in consequence of an illegal operation the person performing it might be charged with murder or manslaughter, but these offences could not be committed with respect to a child in the mother's womb, as the child was not *in rerum natura*. If, however, the child was born alive and subsequently died owing to injuries received *en ventre sa mere*, the offender was liable. In Russell on *Crimes* acts were described as lawful which were done in the course of proper treatment and in the interest of the life or health of the mother. *Midwifery by Ten Teachers* stated that operations of this kind were confined to cases in which the life of the mother would be endangered or her health likely to be permanently damaged by the continuation of the pregnancy. Lord Riddell thought the word "permanent" inaccurate. Induction was not only justifiable, but a duty when the pregnancy indicated grave danger to the mother's health, whether the result was likely to be permanent or not. But it was not justified for the purpose of avoiding the minor risks of pregnancy. The practitioner must not be influenced by the appeals of the patient or her relatives to relieve her of these ordinary risks and discomforts, nor by economic considerations in the case, nor by his compassion for a woman in a distressing situation. He must remember, however, that the mother's life must never be sacrificed for the unborn child, even though she be suffering from incurable disease; on the other hand, the possibility of diseased offspring was no indication for abortion. It could not be denied that there were practitioners ready to seize on any reason to justify abortion when desired by the patient, and offences could not be readily detected in the case of a married woman attended by two medical men. The practitioner dealing with a pregnant unmarried woman was faced with a problem of great difficulty. If he procured abortion his motives were open to question; if he failed to do what was necessary to preserve the life or health of his patient he was liable to grave moral condemnation and possibly legal consequences. The practitioner should always act openly, and seek the support of a second opinion, and if his motives were right he had little to fear. The patient, however, should not be prejudiced by her medical adviser's conscientious scruples. If the practitioner thought abortion necessary, and therefore legally justifiable, but his conscience would not allow him to pro-

cure it, the patient should be made to understand that she was being attended by a doctor whose convictions she might or might not share. Lord Riddell sketched the history of abortion from pagan times, and said that the doctrine that the mother was to be sacrificed or risked for the benefit of the unborn child was a relic of the Dark Ages and was biologically unsound. A point to be noted was that even the Roman Catholic Church discriminated between early and late abortion. The decretal of Gregory IX (1244) defined abortion as homicide if the child had quickened, otherwise not.

Border-line Cases.

Dr. H. RUSSELL ANDREWS, taking the place of Dr. Watts Eden, who was unable to attend, thought that Dr. Fairbairn was going too far when he suggested that the profession in any general way had given up the former definite indications for the induction of abortion. If not, he could only think that Dr. Fairbairn associated with a laxer type of general practitioner than he did himself. Some cases which came to the consultant were easily dealt with, and after investigation a common-sense talk with husband and wife convinced them that the pregnancy ought not to be interrupted. At the other end of the scale were cases in which there could hardly be any difference of opinion that continuation of the pregnancy was fraught with danger to life or possible impairment of health. It was the border-line cases which gave anxiety, and personally he had often had a cowardly wish that the patient's medical adviser had chosen some other consultant. The medical man must sympathize with the tired, exhausted, anxious patient who felt that she could not face the ordeal of many months' disability and ill health, but he realized that he must not allow his judgement to be swayed by sympathy alone, and looked for some definite peg on which to hang his decision one way or the other. The condition was often complicated by what was actually an obsession or fixed idea in the mind of both husband and wife, based on advice given some months or years before, by one or more doctors, that there must not be another pregnancy. On two or three occasions, when he thought that this advice had been given lightly and on insufficient grounds, and remarked that there was a great difference between advising against another pregnancy and destroying life, he was met with the retort that there would not be much difference if only doctors would be more logical. It was impossible to lay down hard and fast rules for the conduct of border-line cases; each case must be judged on its merits. Dr. Andrews then described in detail two cases in which he had been consulted during the last few months, and in which he had felt justified in advising induction.

Criminal and Non-criminal Abortion.
